First Printing, April 1939
Second Printing, September 1942
Third Printing, December 1944

Presentation and Appreciation

A.S.M. Metals Handbook contains approximately five hundred articles on metals and their alloys. These articles were prepared by authors or by committees under the direction and supervision of the Metals Handbook Committee. The men who have prepared Metals Handbook are all specialists and authorities in their particular field. This Handbook has been made possible by the co-operation of a large number of the members of the American Society for Metals. Approximately 2500 members have contributed in some way in the compilation of this Handbook.

Our thanks and appreciation are extended to the authors, to members of all the committees, to the reviewers of articles and to the many firms who have so generously permitted their men to devote hours of valuable time to the preparation of this volume, who by their whole-hearted co-operation have made possible this edition of Metals Handbook.

A considerable portion of Metals Handbook deals with non-ferrous metals and was prepared under the direction of the Non-ferrous Data Sheet Committee of the Institute of Metals Division of the American Institute of Mining and Metallurgical Engineers. We wish to take this opportunity to record the sincere appreciation of the membership of the American Society for Metals for the production of this very valuable portion of Metals Handbook.

The volume is now presented to the members of the American Society for Metals with the hope and belief that it will be of great service not only to the members but to the entire metal industry.

AMERICAN SOCIETY FOR METALS

President

A.S.M. METALS HANDBOOK COMMITTEE 1939 EDITION†

RALPH L. DOWDELL, CHAIRMAN (1939) J. EDWARD DONNELLAN, SECRETARY
University of Minnesota 7301 Euclid Ave., Cleveland

MEMBERS

R. H. ABORN (1939) United States Steel Corp.	O. E. HARDER (1938) Battelle Memorial Institute	R. B. SCHENCK (1939) Buick Motor Co.
E. L. BARTHOLOMEW (1940) United Shoe Machinery Corp.	S. L. HOYT (1938) A. O. Smith Corp.	S. C. SPALDING (1941) American Brass Co.

	G. H. WRIGHT (1926-1929) General Electric Co.

*Deceased.

PREFACE

*I*N THE preparation of *Metals Handbook*, the endeavor has been made to prepare a comprehensive volume of metallurgical subjects pertaining to the manufacture, treatment, and application of metals so that the metallurgist, engineer, student, and all those interested in metals will have readily available an authoritative reference book covering the field of metals and their alloys. In compiling the material for this edition, the committees in charge of the work have selected those subjects having the most extensive interest. It is the aim to make *Metals Handbook* a complete book of reference on the subject of metals and this edition indicates that the attempt towards this end is becoming successful. Additional articles will be added and it will, therefore, eventually include the more specialized subjects dealing with metals.

The same plan for the selection of subjects and for the arrangement and compilation of the subjects in the *Handbook* has been followed that was used in previous editions. This plan, formulated by R. S. Archer, consists of arranging the articles under several major headings as shown in the Table of Contents. *Metals Handbook Committee* has found this system very helpful in assigning subjects to authors and subcommittees and properly classifying them in the *Handbook*.

The material in this *Handbook* has been prepared by men who are all specialists and authorities in their particular field. They obtained the material either from their own researches or from sources considered trustworthy and reliable. The articles were carefully reviewed by *Metals Handbook Committee* and special reviewing committees. It is, however, recommended that the information in this *Handbook* should be interpreted by the reader in the light of his own personal experience and in accordance with his own plant equipment and practices.

It is desired to emphasize that the material published in this *Handbook* is not intended for specifications and should not be interpreted by the reader as such.

The American Society for Metals does not, by the publication of an article in this *Handbook*, insure anyone using such information against liability, nor does the Society assume any liability for infringement of any patent that may now exist or that may be issued later. Also, it should be understood that the publication of any article in this *Handbook* does not constitute a recommendation of any patent or proprietary rights that may be involved.

A considerable portion of this Handbook is devoted to a variety of subjects on nonferrous metallurgy. This is an important section of the Handbook and it is believed that it constitutes a section that meets a valuable need among the many readers. Material for the nonferrous section has been prepared and compiled by members of the Institute of Metals Division of the American Institute of Mining and Metallurgical Engineers through a co-operative arrangement with the American Society for Metals. The Nonferrous Data Sheet Committee of the Institute of Metals has completed a very successful and important program for this edition of Metals Handbook. The completion of this program has aided greatly in developing the nonferrous section of the Handbook. It contains more than ever before information on the properties, technology, and application of nonferrous metals and their alloys. The personnel of the Nonferrous Data Sheet Committee of the Institute of Metals Division was as follows: Jerome Strauss, Chairman; W. L. Fink; W. E. Remmers; E. E. Schumacher; E. M. Wise; and Lyall Zickrick.

We especially wish to express our thanks and appreciation to the members of Metals Handbook Committee, its predecessors, its subcommittees, to the individual authors, to the Nonferrous Data Sheet Committee of the Institute of Metals Division of the American Institute of Mining and Metallurgical Engineers, and the many reviewers who have given so generously of their time and technical information in the preparation of this Handbook.

We are indebted to Ralph Dowdell, Professor of Metallography, School of Mines and Metallurgy, University of Minnesota, and Miss Carrie Green, Teaching Assistant in Metallography, School of Mines and Metallurgy, University of Minnesota, for the preparation of the index. They have devoted much time and thought in the endeavor to prepare an adequate index for this volume. It is our hope and belief that their endeavors are successful.

The users of Metals Handbook will be rendering a service if they will point out any errors that may come to their attention so that corrections can be properly made in future printings.

Each member of the Society should feel free to offer his constructive criticisms and suggestions, all of which are an indispensable auxiliary to the preparation and enlargement of future editions of this Handbook. It is only by the continuation of such co-operation that we may expect to have Metals Handbook continue its growth in the future as it has in the past.

TABLE OF CONTENTS

See Index in Back of Book

Ferrous Section

General Data

	Page
Definitions of Heat Treating Terms.....	3
Glossary of X-Ray Terms.....	11
Tool Steel Trade Names.....	18
Corrosion and Heat Resisting Alloys, Trade Names.....	38
Decimal and Metric Equivalents of Parts of an Inch.....	54
Interconversion Table for Units of Energy.....	56
Wire and Sheet Gages.....	57
Weights of Steel Bars.....	58
Temperature Conversion Data.....	65
Pyrometric Cones.....	67
Greek Alphabet.....	67

Glossary of Selected Iron and Steel Terms and Definitions of Terms Relating to Heat Treatment Operations*

(Especially as Related to Ferrous Alloys)

Foreword to Definitions—In the development of the knowledge of heat treating operations some confusion has arisen concerning the terms commonly used. For example, the term “annealing” is applied by some to any operation of heating and cooling which results in softening, while as applied by others, the term does not mean softening primarily but describes a treatment consisting in heating above the upper critical temperature in steel and cooling very slowly. Similar confusion has for many years attended the use of the terms “hardening” and “tempering.”

In any attempt to define accurately commonly used terms, it is necessary to decide whether the terms are to relate to the operation performed, or to the properties thus determined; in general, the terms given will relate to the operations performed, though this is not always possible.

By critical temperatures, or by a critical temperature range, is meant those temperatures or that temperature range at which and in which iron-carbon alloys undergo transformation. Fig. 1 represents those schematically; all temperatures indicated are designated as transformation temperatures as determined on heating—this is the meaning of the *c* included in each term; it will be understood that Fig. 1 is not intended to give exact temperatures, for these vary with the rate of heating, are quite different on cooling, and vary with a number of factors. In Fig. 1 each line is appropriately designated; modern usage is veering toward the use of simple letters to designate the various lines, and these are also indicated in Fig. 1.

Fig. 1.

Acid Bottom and Lining—The inner bottom and lining of a melting furnace composed of materials having an acid reaction in the melting process. The materials may be sand, siliceous rock, or silica bricks.

Acid Brittleness—The brittleness induced in steel, especially wire or sheet, when pickled in dilute acid for the purpose of removing scale or upon electroplating. This brittleness is commonly attributed to the absorption of hydrogen.

Acid Steel—Steel melted in a furnace with an acid (siliceous) bottom and lining and under a slag which is dominantly siliceous.

Aging—The spontaneous change in properties of a metal which occurs at relatively low temperature after a final heat treatment or a final cold working operation. Aging is a process in which the trend is toward a restoration of real equilibrium, and away from an unstable condition induced by a prior operation. The fundamental reaction involved is generally one of precipitation, sometimes submicroscopic. The method employed to bring about aging consists of exposure to a favorable temperature subsequent to (a) a relatively rapid cooling from some elevated temperature (quench aging) or (b) a limited degree of cold work (strain aging).

Air Hardening Steel—An alloy steel which does not require quenching from a high temperature to harden, but which is hardened by simply cooling in air from above its critical temperature range.

Alloy—A mixture with metallic properties composed of two or more elements of which at least one is a metal.

Alloy Elements—Chemical elements comprising an alloy; in steels usually limited to the metallic elements added to steel to modify its properties.

Alpha Iron—See the article “Iron-Carbon Diagram” in this Handbook.

Amorphous—Noncrystalline.

Annealing—A heating and cooling operation implying usually a relatively slow cooling.

Note—Annealing is a comprehensive term. The purpose of such a heat treatment may be:

- (a) To remove stresses.
- (b) To induce softness.
- (c) To alter ductility, toughness, electrical, magnetic, or other physical properties.
- (d) To refine the crystalline structure.
- (e) To remove gases.
- (f) To produce a definite microstructure.

In annealing, the temperature of the operation and the rate of cooling depend upon the material being heat treated and the purpose of the treatment.

*Prepared by the Committee on Definitions: R. F. Mehl, Chairman; O. H. Mathewson, R. H. Aborn, and R. B. Schenck.

Certain specific heat treatments coming under the comprehensive term "annealing" are:

A. Full Annealing—Heating iron-base alloys above the critical temperature range, holding above that range for a proper period of time, followed by slow cooling to below that range.

Note—The annealing temperature is generally about 100°F. above the upper limit of the critical temperature range, and the time of holding is usually not less than 1 hr. for each inch of section of the heaviest objects being treated (see tool steel section in this Handbook for tool steel practice). The objects being treated are ordinarily allowed to cool slowly in the furnace. They may, however, be removed from the furnace and cooled in some medium which will prolong the time of cooling as compared to unrestricted cooling in the air.

B. Process Annealing—Heating iron-base alloys to a temperature below or close to the lower limit of the critical temperature range followed by cooling as desired.

Note—This heat treatment is commonly applied in the sheet and wire industries, and the temperatures generally used are from 1020-1200°F.

C. Normalizing—Heating iron-base alloys to approximately 100°F. above the critical temperature range followed by cooling to below that range in still air at ordinary temperature.

D. Patenting—Heating iron-base alloys above the critical temperature range followed by cooling below that range in air, or in molten lead or a molten mixture of nitrates or nitrites maintained at a temperature usually between 800-1050°F., depending on the carbon content of the steel and the properties required of the finished product.

Note—This treatment is applied in the wire industry to medium or high carbon steel as a treatment to precede further wire drawing.

E. Spheroidizing—Any process of heating and cooling steel that produces a rounded or globular form of carbide.

Note—The spheroidizing methods generally used are

(1) Prolonged heating at a temperature just below the lower critical temperature, usually followed by relatively slow cooling.

(2) In the case of small objects of high carbon steels, the spheroidizing result is achieved more rapidly by prolonged heating to temperatures alternately within and slightly below the critical temperature range.

(3) Tool steel is generally spheroidized by heating to a temperature of 1380-1480°F. for carbon steels and higher for many alloy tool steels, holding at heat from 1-4 hours and cooling slowly in the furnace.

F. Tempering—(also termed drawing)—Reheating hardened steel to some temperature below the lower critical temperature, followed by any desired rate of cooling.

Note—Although the terms "tempering" and "drawing" are practically synonymous as used in commercial practice, the term "tempering" is preferred.

G. Malleabilizing—An annealing operation performed on white cast iron partially or wholly to transform the combined carbon to temper carbon, and in some cases wholly to remove the carbon from the iron by decarburization.

Note—Temper carbon is free graphitic carbon in the form of rounded nodules composed of an aggregate of minute crystals.

H. Graphitizing—Graphitizing is a type of annealing for gray cast iron whereby some or all of the combined carbon is transformed to free graphitic carbon.

Austenite—See the article "Iron-Carbon Diagram" in this Handbook.

Banded Structure—A segregated structure of nearly parallel bands which run in the direction of working.

Bark—The decarburized skin or layer just beneath the scale found after heating steel in an oxidizing atmosphere.

Basic Bottom and Lining—The inner lining and bottom of a melting furnace composed of materials having a basic reaction in the melting process. The materials may be crushed burnt dolomite, magnesite, magnesite bricks, or basic slag.

Basic Steel—Steel melted in a furnace with a basic bottom and lining and under a slag which is dominantly basic.

Bessemer Process—A process for making steel by blowing air through molten pig iron contained in a suitable vessel. The process is one of rapid oxidation mainly of silicon and carbon.

Beta Iron—See the article "Iron-Carbon Diagram" in this Handbook.

Billet—See *bloom*.

Billet Mill—See *blooming mill*.

Binary Alloy—An alloy containing two elements, apart from minor impurities.

Black Annealing—A process of box annealing of sheets prior to tinning whereby a black color is imparted to the surface of the product.

Blast Furnace—A shaft furnace supplied with air blast, usually hot, for producing pig iron by smelting iron ore. The furnace is continuous in operation, the raw materials (iron ore, coke, and limestone) are charged at the top, and the molten pig iron and slag are collected at the bottom and are tapped out at intervals.

Bliater—A defect in metal produced by gas bubbles either on the surface or formed beneath the surface. Very fine blisters are called pinhead or pepper blisters.

Bliater Bar—Wrought iron bars impregnated with carbon and formerly used in the manufacture of crucible steel. Also called *bliater steel*.

Bloom (slab, billet, sheet bar)—Semifinished products of rectangular cross section with rounded corners, hot rolled from ingots. The chief differences are in cross sectional area, in ratio of width to thickness, and in their intended use. American Iron and Steel Institute Manual classifies general usage as follows:

Type	Width, in.	Thickness, in.	Cross Section Area, sq. in.
Bloom	Width equals thickness		36 (min.)
Billet	1½ (min.)	1½ (min.)	2¼-36
Slab	10+ (min.)	1½ (min.)	16 (min.)
Sheet bar	8-16	¼-2*	2-32*

*Calculated from weight range 7-54 lb. per lineal foot.

Rerolling quality blooms, slabs, and billets are intended for hot rolling into shapes, plates, strip, bars, and wire rod.

Forging quality blooms, billets, and slabs are intended for conversion into forgings.

Sheet bar is converted by rolling into sheet, black plate, and tin plate.

Blooming Mill—A mill used to reduce ingots to blooms, billets, slabs, or sheet bars. Depending upon the product, the mill is called a blooming mill (cogging mill in England), a billet mill, or a slabbing mill.

Blowhole—A hole produced during the solidification of metal by evolved gas which, in failing to escape, is held in pockets.

Blue Annealing—A process of annealing sheets after rolling. The sheets, if fairly heavy, are allowed to cool slowly after the hot rolling; if of lighter gage, as is usually the case, they are passed singly through an open furnace for heating to the proper annealing temperature. As the name indicates, the sheets have a bluish-black appearance.

Blue Brittleness—Brittleness occurring in steel when worked in the temperature range of 300-700°F., or when cold after being worked within this temperature range.

Box Annealing—Softening steel by heating, usually at a subcritical temperature, in a suitable closed metal box or pot to protect it from oxidation, employing a slow heating and cooling cycle; also called close annealing or pot annealing.

Bright Annealing—A process of annealing, usually with reducing gases, such that surface oxidation is reduced to a minimum, thereby yielding a relatively bright surface.

Burning—The heating of a metal to temperatures sufficiently close to the melting point to cause permanent injury. Such injury may be caused by the melting of the more fusible constituents, by the penetration of gases such as oxygen into the metal with consequent reactions, or perhaps by the segregation of elements already present in the metal.

Capped Steel—See *rimmed steel*.

Carbon Free—Metals and alloys which are practically free from carbon.

Carbon Steel—Steel which owes its properties chiefly to various percentages of carbon without substantial amounts of other alloying elements; also known as ordinary steel or straight carbon steel or plain carbon steel.

Carbonization—Coking or driving off the volatile matter from fuels such as coal and wood. (Carbonizing should not be confused with "carburizing".)

Carburizing (Cementation)—Adding carbon to the surface of iron-base alloys by heating the metal below its melting point in contact with carbonaceous solids, liquids, or gases.

Note—The term "carbonizing" is inadvisable and its use should be discouraged.

Case—The surface layer of an iron-base alloy which has been made substantially harder than the interior by the process of case hardening.

Case Hardening—A heat treatment or a combination of heat treatments in which the surface layer of an iron-base alloy is made substantially harder than the interior by altering its composition (carburizing or cyaniding, both of which are ordinarily followed by quenching, or by nitriding).

Cast Steel—Any object made by pouring molten steel into molds.

Casting Strains—Strains accompanied by internal stresses resulting from the cooling of a casting.

Cementite—See the article "Iron-Carbon Diagram" in this Handbook.

Chill Cast Pig—Pig iron cast into metal molds or chills. If a machine is used the product is known as machine cast pig.

Chipping—One method for removing seams and other surface defects with chisel or gouge, so that the defects will not be worked into the finished product. If the defects are removed by means of gas cutting the term "deseaming" or "scarfing" is used. Chipping is often employed simply to remove metal apart from defects.

Cleavage Plane—It is frequently possible to fracture a crystal of a metal or other substance so that the surface of fracture is smooth and plane, and always parallel to some definite crystallographic plane. This crystallographic plane is known as a cleavage plane. A substance may cleave on more than one crystallographic plane.

Cogging—Rolling or forging ingots to reduce them to blooms.

Cogging Hammer—A forging hammer used to reduce ingots to blooms.

Cogging Mill—See *blooming mill*.

Cold Rolling—See *cold working*.

Cold Shut—A defect produced during casting of molten metal which may result from splashing, surging, interrupted pouring, or the meeting of two streams of metal coming from different directions. It may be due to the freezing of one surface before the other metal flows over it, or to the presence of interposing surface films or dirt on cold sluggish metal, or to any factor that will prevent a perfect union where two surfaces meet that should fuse and blend.

Cold Working—Plastic deformation of a metal at a temperature low enough to insure strain hardening.

Combined Carbon—All the carbon in iron or steel which is combined with iron or alloying elements to form carbide.

Core—The interior portion of an iron-base alloy which is substantially softer than the surface layer as the result of case hardening.

Note—Also, that portion of a forging removed by trepanning; the inner part of a rolled section of rimmed steel as distinct from the rimmed portion or rim; a body of sand or other material placed in a mold to produce a cavity in a casting.

Cored Structure—A grain structure having composition gradients caused by the progressive freezing of the components in different proportions; the term "zonal structure" is in general preferable. In dendrites the cored or zonal structure is manifested by solvent-rich crystal axes and solute-rich interstices.

Critical Points—See the article "Iron-Carbon Diagram" in this Handbook.

Critical Range—See *critical points*.

Critical Temperature—See *critical points*.

Crop—The end or ends of an ingot containing the pipe or other defects which are cut off and discarded; also termed "crop end" and "discard."

Cup Fracture—The form of fracture of a tension test specimen when the exterior portion is extended and the interior relatively depressed, so that it looks like a cup, as the name implies. When only a portion of the exterior is extended the terms "half cupped" and "quarter cupped" are used, as the case may be.

Cupping—A defect in wire which causes it to break with a cup fracture accompanied by very little reduction of area.

Cyaniding—Surface hardening by carbon and nitrogen absorption of an iron-base alloy article or portion of it by heating at a suitable temperature in contact with a cyanide salt, followed by quenching.

Decalescence—The absorption of heat which occurs when steel is heated through the Ac₁ point.

Decarburization—The removal of carbon (usually refers to the surface of solid steel) by the (normally oxidizing) action of media which react with carbon.

Dendrite—A crystal formed by solidification, or in any other way, having many branches and a tree-like pattern; also termed "pine tree" and "fir tree" crystals.

Deseaming—See *chipping*.

Differential Heating—Heating conducted in such a way that various portions of an object attain different temperatures so that upon cooling different properties are produced.

Discard—See *crop*.

Dissolved Carbon—Carbon in solution in either the liquid or solid state.

Divorced Cementite—The cementite resulting from partial or complete spheroidization, frequently observed in some slowly cooled steels, particularly fine grained, aluminum killed steel.

Drawing Back—See *tempering under annealing*.

Elongation—The amount of permanent extension in the vicinity of the fracture in the tension test; usually expressed as a percentage of the original gage length, such as 25% in 2 in. It may also refer to the amount of extension at any stage in any process which continuously elongates a body, as in rolling.

Endurance Limit—A limiting stress, below which metal will withstand without fracture an indefinitely large number of cycles of stress. If the term is used without qualification, the cycles of stress are usually such as to produce complete reversal of flexural stress. Above this limit failure occurs by the generation and growth of cracks until fracture results in the remaining section.

Endurance Ratio—The ratio of the endurance limit for cycles of reversed flexural stress to the tensile strength.

Equilibrium—See the article "Iron-Carbon Diagram" in this Handbook.

Eutectic Alloy—The composition in an alloy system at which two descending liquidus curves in a binary system or three descending liquidus surfaces in a ternary system intersect at a point. Such an alloy has thus a lower melting point than neighboring compositions. More than one eutectic composition may occur in a given alloy system.

Eutectoid Steel—A steel of the eutectoid composition. Composition S on the iron-carbon diagram. This composition in pure iron-carbon alloys is 0.80% C, but variations from this composition are found in commercial (impure) steels, and particularly in alloy steels in which the eutectoid composition is usually lower.

Exfoliation—The spalling or flaking off of the outer layer of an object.

Fatigue—The phenomenon of the progressive fracture of a metal by means of a crack which spreads under repeated cycles of stress.

Fatigue Limit—Usually used as synonymous with endurance limit.

Ferrite—See the article "Iron-Carbon Diagram" in this Handbook.

Ferrite Ghost—A faint band of ferrite.

Ferroalloy—An alloy of iron with a sufficient amount of some element or elements, such as manganese, chromium, or vanadium, for use as a means of introducing these elements into steel by admixture to molten steel.

Fiber—A characteristic of wrought metal manifested by a fibrous or woody appearance of fractures and indicating directional properties. Fiber is caused chiefly by the extension in the direction of working of the constituents of the metal, both metallic and nonmetallic. This term also refers to the characteristic reorientation of the crystalline particles of the metal produced by a given deformation process; see "fibering" in the Glossary of Terms used in X-ray Metallography.

Fiber Stress—Local unit stress at a point or line on a section over which stress is not uniform, such as the cross section of a beam under a bending load.

Fin—See *flash*.

Finished Steel—Steel which is ready for the market without further work or treatment. Blooms, billets, slabs, sheet bars, and wire rods are termed semifinished.

Finishing Temperature—The temperature at which hot mechanical working of metal is completed.

Fir Tree Crystal—See *dendrite*.

Flakes (or "snow flakes")—Internal fissures in large steel forgings or massive rolled shapes. In a fractured surface or test piece they appear as sizeable areas of silvery brightness and coarser grain size than their surroundings. Sometimes known as "chrome checks" and (when revealed by machining) "hairline cracks." Not to be confused with "woody fracture."

Flash—A thin fin of metal formed at the sides of a forging or weld where a small portion of the metal is forced out between the edges of the forging or welding dies.

Forging Strains—Elastic strains resulting from forging or from cooling from the forging temperature.

Fracture—The irregular surface produced when a piece of metal is ruptured or broken.

Fracture Test—Breaking a piece of metal for the purpose of examining the fractured surface to determine the structure or carbon content of the metal or the presence of internal defects.

Free Ferrite—Ferrite formed from austenite on cooling, without simultaneous rejection of carbon.

Full Annealing—See *annealing*.

Fusible Alloys—A group of nonferrous alloys which melt at relatively low temperatures. They usually consist of bismuth, cadmium, lead, and tin in various proportions, and iron only as an impurity.

Gamma Iron—A crystal form of iron (face-centered cubic) stable between A_3 and A_4 . See the article "Iron-Carbon Diagram" in this Handbook.

Ghost, Ghost Lines, or Ghost Structure—See *ferrite ghost*.

Globular Cementite—See *spheroidal cementite*.

Grains—Individual crystals in metals.

Grain Growth—An increase in the grain size of metal.

Granular Pearlite (also globular pearlite and divorced pearlite)—A structure formed from ordinary lamellar pearlite by long annealing of steel at a temperature below but near to the lower critical point, causing the cementite to spheroidize in a ferrite matrix. Since "pearlite" connotes a lamellar structure, this name is not recommended; the word "spheroidite" has been proposed.

Granulation—The recrystallization of columnar crystals and dendrites in freshly solidified steel to more or less equiaxed grains at temperatures near the solidus.

Graphitizing—See *annealing*.

Hair Seam—See *seam*.

Hardening—Heating and quenching certain iron-base alloys from a temperature either within or above the critical temperature range for the purpose of producing a hardness superior to that obtained when the alloy is not quenched. Usually restricted to the formation of martensite.

Heat Tinting—Heating a specimen with a suitable surface in air for the purpose of developing the structure by oxidizing or otherwise affecting the different constituents.

Heat Treatment—An operation or combination of operations involving the heating and cooling of a metal or alloy in the solid state for the purpose of obtaining certain desirable conditions or properties.

Note—Heating and cooling for the sole purpose of mechanical working are excluded from the meaning of this definition.

Hot Shortness—Brittleness in metal when hot.

Hot Top—See *sinkhead*.

Hot Working—Plastic deformation of metal at a temperature high enough to prevent strain hardening.

Hypereutectoid Steel—A steel containing more than the eutectoid percentage of carbon; see *eutectoid steel*.

Hypoeutectoid Steel—A steel containing less than the eutectoid percentage of carbon; see *eutectoid steel*.

Impact Test—Tensile and bend impact tests or test specimens are described in other parts of the Handbook.

Inclusions—Particles of impurities, usually oxides, sulphides, silicates, and such which are mechanically held during solidification or which are formed by subsequent reaction of the solid metal.

Ingot—A special kind of casting for subsequent rolling or forging.

Ingot Iron—An open hearth iron very low in carbon, manganese, and other impurities.

Killed Steel—A steel sufficiently deoxidized to prevent gas evolution during solidification. The top surface of the ingot freezes immediately and subsequent shrinkage produces a central pipe. A *semikilled steel*, having been less completely deoxidized, develops sufficient gas evolution internally in freezing to replace the pipe by a substantially equivalent volume of rather deep-seated blowholes. (See section on Open Hearth Process.)

Lap—A surface defect appearing as a seam caused from folding over hot metal, fins, or sharp corners and then rolling or forging, but not welding, them into the surface.

Lap Weld—A term applied to a weld formed by lapping two pieces of metal and then pressing or hammering, particularly, to the longitudinal joint produced by a welding process for tubes or pipe in which the edges of the skelp are beveled or scarfed so that when they are overlapped they can be welded together. The product is known as lap weld or lap welded pipe.

Ledeburite—The cementite-austenite eutectic forming at point C on the iron-carbon diagram. During cooling the austenite in ledeburite may transform to ferrite and carbide-cementite. It is found in cast iron and high alloy steels such as high speed steel.

Liquidus—The line on a temperature-composition (phase) diagram of a binary system, or surface on a diagram of a ternary system, representing the temperatures at which freezing begins on cooling or melting ends on heating under equilibrium conditions.

Lüder's Lines (stretcher-strains, flow figures)—Elongated surface markings that appear on the surface of some materials, particularly iron and low carbon steel, when deformed just past the yield point. These markings lie approximately parallel to the direction of maximum shear stress and are the result of localized yielding. They consist of depressions when produced in tension and of elevations when produced in compression; they may be made evident by localized roughening of a polished surface or by localized flaking of scale from a scaled surface.

Lute—A mixture of fire clay used to seal up cracks between crucible and cover or between annealing box and cover to make a gas tight joint when heat is to be applied; also applied to the operation.

Macroscopic—Visible either with the naked eye or under low magnifications (up to about 10 diameters).

Macrostructure—The structure and internal condition of metals as revealed on a ground or polished (and sometimes etched) sample, by either the naked eye or under low magnifications (up to about 10 diameters).

Malleablizing—See *annealing*.

Martensite—A microconstituent or structure in quenched steel characterized by an acicular or needle-like pattern on the surface of polish. It has the maximum hardness of any of the decomposition products of austenite.

Note—Martensite is a transition lattice formed by the partial transformation of austenite. It is not an equilibrium lattice and thus not an equilibrium phase. The lattice is tetragonal.

Matrix—The ground mass or principal substance in which a constituent is embedded.

Mechanical Properties—Those properties that reveal the reaction, elastic and inelastic, of a material to an applied force, or that involve the relationship between stress and strain, for example, Young's modulus, tensile strength, fatigue limit. These properties have often been designated as physical properties, but the term mechanical properties is much to be preferred.

Mechanical Testing—Testing methods by which mechanical properties are determined.

Mechanical Working—Subjecting metal to pressure exerted by rolls, presses, or hammers, to change its form, or to affect the structure and therefore the mechanical and physical properties.

Metalloid—Originally a chemical element that has the physical characteristics of a metal such as metallic conduction and metallic luster, but which behaves chemically as both nonmetal and metal; that is, it reacts directly with other metals yet also combines with the halogens to form salts. Typical examples are arsenic, antimony, and tellurium. With increasing knowledge of metallic compounds the term has become less useful, and it is now considered obsolete. In metallurgical practice it has come to have a special meaning as applying to the elements such as C, Si, P, S, and Mn, which are commonly present in small amounts in iron and steel.

Modulus of Elasticity—The ratio, within the limit of elasticity, of the stress to the corresponding strain. The stress in pounds per square inch is divided by the elongation in fractions of an inch for each inch of the original gage length of the specimen.

Network Structure—A structure in which the grains or crystals of one constituent are partially or entirely surrounded with envelopes of another constituent. The appearance of an etched section through the crystals is that of a network.

Neumann Bands—Mechanical twins in alpha iron, in the form of narrow bands parallel to planes of the form {211}. Customarily formed only on deformation by impact, but in some alloys (silicon-ferrite) and particularly at low temperatures formed more readily, as in ordinary cold working processes.

Nitriding—Adding nitrogen to iron-base alloys by heating the metal in contact with ammonia gas, or other suitable nitrogenous material.

Note—Nitriding is conducted at a temperature usually in the range 935-1000°F. and produces surface hardening of the metal without quenching. See article on "Nitriding."

Normalizing—See *annealing*.

Overheating—Heating to such high temperatures that the grains have become coarse, thus impairing the properties of the metal.

Patenting—See *annealing*.

Pearlite—The lamellar aggregate of ferrite and carbide resulting from the direct transformation of austenite at Ar₁.

Note—It is recommended that this word be reserved for the microstructures consisting of thin plates or lamellae—that is, those that may have a pearly luster in white light. The lamellae can be very thin and resolvable only with the best microscopic equipment and technique.

Permanent Mold—A mold ordinarily of metal which is used repeatedly for the production of many castings of the same form. Not commonly applied to ingot molds.

Permanent Set—Permanent deformation.

Phosphorus Banding—See *ferrite ghost*.

Physical Properties—Those properties familiarly discussed in physics, exclusive of those described under mechanical properties; for example, density, electrical conductivity, coefficient of thermal expansion. This term has often been used to describe mechanical properties, but this usage is not recommended. (See mechanical properties.)

Physical Testing—Testing methods by which physical properties are determined. This term is also inadvisedly used to mean the determination of the mechanical properties.

Piercing—Producing a hole in metal by forcing an instrument through it. Usually refers to making steel tubes from solid steel bars.

Pig Iron—See the article "Cast Iron" in this Handbook.

Pine Tree Crystals—See *dendrite*.

Pinhead Blister—See *blister*.

Pipe—A cavity formed in metal (especially ingots) during the solidification of the last portion of liquid metal. Contraction of the metal causes this cavity or pipe.

Pit—A sharp depression in the surface of metal.

Pot Annealing—See *box annealing*.

Pouring—Pouring molten metal from the ladle into ingot molds or other types of molds (as, for example, in castings).

Process Annealing—See *annealing*.

Quaternary Alloy—An alloy containing four principal elements.

Quenching—Rapid cooling by immersion in liquids or gases or by contact with metal.

Recalcinescence—The liberation of heat when steel is cooling through the Ar₁ point.

Red Shortness—Brittleness in steel when it is red hot.

Reduction in Area—The difference between the original cross sectional area and that of the smallest area at the point of rupture. It is usually stated as a percentage of the original area; also called "contraction of area."

Refining Temperature or Heat—A temperature employed in heat treatment to refine the structure, in particular, the grain size. Usually just above Ac₃ in steel.

Regenerative Quenching—A double quenching of carburized objects to refine the case and core. The first quench is from a high temperature to refine the core, and the second quench is from a lower temperature to further refine and harden the case.

Rimmed Steel—An incompletely deoxidized steel normally containing less than 0.25% carbon and having the following characteristics: (a) During solidification an evolution of gas occurs sufficient to maintain a liquid ingot top ("open" steel) until a side and bottom rim of substantial thickness has formed. If the rimming action is intentionally stopped shortly after the mold is filled the product is termed *capped steel*. (b) After complete solidification, the ingot consists of two distinct zones: A rim somewhat purer than when poured and a core containing scattered blowholes with a minimum amount of pipe and having an average metalloïd content somewhat higher than when poured and markedly higher in the upper portion of the ingot.

Riser—See *sinkhead*.

Seab (Seabby)—A rough projection on a casting caused by the mold breaking or being washed by the molten metal, or occurring where the skin from a blowhole has partly burned away and is not welded.

Scarfing—See *chipping*.

Seam—A crack on the surface of metal which has been closed but not welded; usually produced by blowholes which have become oxidized. If very fine, a seam may be called a hair crack or hair seam; also see *cold shut* and *lap*.

Secondary Hardening—Hardness developed by tempering high alloy steels.

Self Hardening Steel—A steel carrying sufficient carbon or alloy content (or both) to form martensite through rapid heat removal from a locally heated portion (as in welding) by conduction into the surrounding cold metal. See also *air hardening*.

Semifinished—See *finished*.

Sheet Bar—See *bloom*.

Shortness—Brittleness in metal

Silky Fracture—A steel fracture having a very smooth fine grain or silky appearance.

Sinkhead or Hot Top (also called a **Riser** when applied to castings)—A heat insulated reservoir for excess metal on top of an ingot mold or casting mold which feeds the shrinkage of the ingot or the casting.

Skelp—A plate of steel or wrought iron from which pipe or tubing is made. This is done by rolling the skelp up longitudinally into shape and welding or riveting the edges together.

Slab—See *bloom*.

Slabbing Mill—A heavy plate mill usually of the two-high universal type.

Slip Bands—A series of parallel lines running across a crystalline grain and produced by deforming the body after the surface on which these lines appear has been polished. They are traces of the slip planes, or planes joining the displaced crystalline blocks or lamellae, and may be distinguished from twin markings by repolishing and etching: Twin markings will reappear, but slip lines will not.

Slip Plane—See *slip bands*

Soaking—Holding steel at an elevated temperature for the attainment of uniform temperature throughout the piece.

Solidification Range—Temperature range through which metal freezes or solidifies.

Solidus Line—The line on a phase diagram below which (at lower temperature) the alloy is entirely solid under equilibrium conditions.

Sonims—Solid nonmetallic inclusions in a metal or alloy.

Sorbite—A late stage in the tempering of martensite, when the carbide particles have grown so that the structure has a distinctly granular appearance. Further and higher tempering causes globular carbides to appear clearly.

Note—Many times the term sorbite is erroneously given to an imperfectly developed pearlite or mixed structure in steel.

Spalling—The cracking and flaking of small particles of metal from the surface.

Spheroidal or Spheroidized Cementite—The globular condition of iron carbide resulting from a spheroidizing treatment (see under *annealing*). The initial structure may be either pearlitic or martensitic.

Note—The term "spheroidized pearlite" should be avoided, even when the structure is undoubtedly the result of spheroidizing anneal of a pearlitic steel. The term "spheroidite" has been proposed.

Spheroidizing—See *annealing*.

Spiegel (also Spiegeleisen)—A pig iron containing 15-30% manganese and 4.5-6.5% carbon.

Stead's Brittleness—A condition of brittleness yielding rectangular transcrystalline fractures in the coarse grain structure produced by prolonged annealing of thin sheets of very low carbon steel previously rolled at a relatively low temperature (below 1300°F.).

Tapping—Removing molten steel from the melting furnace by opening the tap hole and allowing the steel to run into the ladle.

Teeming—See *pouring*. Usually refers to pouring of metal into molds.

Tempering—See *annealing*.

Temper Carbon—A form of graphite in iron-base alloys produced by heating below the melting point.

Ternary Alloy—An alloy containing three principal elements.

Troostite—A microconstituent of hardened and tempered steel which etches rapidly and therefore usually appears dark. It consists of a very fine aggregate of ferrite and cementite and is not resolved under the microscope.

Note—Two entirely different structures are frequently confused and called troostite. The nodular quick etching microconstituent, found in steels which are cooled just too slowly to be fully martensitic, can be resolved into very fine pearlite. It is recommended that the use of the term troostite or "quenching or nodular troostite" to denote this structure be avoided. "Temper troostite" is the first product of the tempering of martensite and consists of sub-microscopic particles of carbide in ferrite, and is frequently indistinguishable in general appearance from a quickly etching fine pearlite. If the word troostite is to be retained it should be reserved for temper troostite. It changes on higher tempering by indistinguishable degrees into sorbite.

Twin Crystals (twins, twinned crystals)—A crystal grain in which the crystal lattices of two parts are related in orientation to each other as mirror images across the interface, which is known as the twinning plane.

Twin Bands—In a polished and etched section, a band across a crystal grain, brought by twinning into relation with the main body of the grain as described above.

Widmanstätten Structure—When a new solid phase forms from a parent solid phase, such as ferrite from austenite, the new phase generally develops plates parallel to lattice planes of a single form in the parent phase, for example, the four families of octahedral planes in austenite. On the polished and etched surface the traces of these plates intersect in a geometrical pattern. Needles and polyhedra may also form. The orientation of the lattice in the new phase is related crystallographically to the orientation of the lattice in the parent phase. Familiarly seen in cast steel and in overheated wrought steel when cooled rather rapidly, but may occur in any alloy in which a phase change occurs.

Wire Rod—A semifinished product from which wire is made. It is generally of circular cross section approximately $\frac{1}{4}$ in. in diameter.

Woody Fracture—A descriptive term for fracture of sound though dirty steel, frequently also reedy or conchoidal in appearance, and often containing discernable slag particles. Woody fractures sometimes contain many small silvery areas, too numerous and small to be correctly termed "flakes", and of a different nature.

Work Hardness—Hardness developed in metal resulting from cold working.

Yield Point—The load per unit of original cross section at which, in soft steel, a marked increase in deformation occurs without increase in load. In other steels and in nonferrous metals, "yield point" is the stress corresponding to some definite and arbitrary total deformation, permanent deformation or slope of the stress deformation curve; this is more properly termed the yield strength.

Yield Strength—Stress corresponding to some fixed permanent deformation such as 0.1 or 0.2% offset from the modulus slope.

Young's Modulus—See *modulus of elasticity*.

Glossary of Terms Used in X-Ray Metallography

By Dr. L. W. McKeehan*

This glossary is primarily intended for those who, while not themselves conducting experiments or tests, in which X-rays are used, have occasion to consult publications in this field. It may have secondary value to those who prepare such publications and who wish to use terms that are unambiguous. A part of the glossary has appeared in the Proceedings of the A.S.T.M.¹ with a report of its Committee on X-Ray Metallography. It is here revised and extended and is supplemented by a list of German terms with their English equivalents. English compound nouns have generally been hyphenated, although the hyphen tends to drop as the terms become more familiar.

A (abbreviation)—Ångström unit, 10^{-8} cm.; also written Å.U., Å.U., Å.

absorber (for X-rays)—A sheet of matter placed between the source of X-radiation and the place where it is detected or measured. When the absorber contains elements so chosen that the intensity of X-rays with undesired wave lengths is especially reduced, the absorber is usually called a filter.

absorption coefficient (for X-rays in a substance)—The rate of decrease, per unit distance traversed in a substance, of the natural logarithm of the intensity of a parallel beam; usually written μ .

absorption-limit—See limit.

amorphous—Without crystal structure, so that the X-ray diffraction-pattern is like that of a liquid.

angle—See glancing angle.

Ångström unit—Å, 10^{-8} cm.

anisotropic—Having different properties in different directions.

anticathode (in X-ray tubes)—The part of the anode which receives most of the cathode-rays, and in which the target, if any, is mounted.

asterism (in X-ray diffraction-patterns)—The appearance of streaks or bands approximately along radii of the pattern.

axial ratio (in crystals)—In the tetragonal system and in the hexagonal division of the hexagonal system, the ratio of the parameter for the principal crystallographic axis of highest multiplicity to the parameter for either one of the other principal axes, usually written $C = c/a$; in less symmetrical systems the continued ratio of all three parameters, usually written $a:b:c$.

axis (crystal)—One of three noncoplanar intersecting lines, fixed with respect to a crystal, which meet any crystal plane at points whose distances from the intersection of the axes, in terms of three parameters (a , b , and c), one for each axis, are in the ratios of small integers; the principal crystal axes are those about which the symmetry is the highest possible to the crystal considered. Less properly, the length of an edge of the unit cell. See parameter.

axis of symmetry—A line in a crystal about which a rotation through $360^\circ/N$, where N is 2, 3, 4 or 6, with or without a translation parallel to the line and with or without a reflection in a plane perpendicular to the line, replaces every element (point, line, and plane) of the crystal by an equivalent element. The axis is said to be N -fold and is a rotation-axis if neither translation nor reflection is involved, is a screw-axis if any other than a primitive translation is involved, and is a rotatory-reflection-axis (N not equal to 3) if reflection is involved.

back reflection—X-ray diffraction at deviations near 180° , especially useful in precise measurement of interplanar distances.

balanced filters (for X-rays)—A pair of filters adjusted to give the same absorption except in the range of wave lengths lying between their characteristic absorption-limits. When used alternately the difference in effect, if any, is due to X-rays having wave lengths in this range.

basal plane—In tetragonal and hexagonal crystals, a plane perpendicular to the c -axis.

beam (X-ray)—A nearly parallel group of X-rays from a common source.

body—See bulb.

body-centered (concerning space-lattices)—Having the equivalent lattice-points at the corners of the unit cell, and at its center; sometimes called centered, or space-centered.

Bragg equation (for X-ray reflection)—The equation $n\lambda = 2d\sin\theta$; see also reflection.

Bragg method (for X-ray or crystal analysis)—Using monochromatic or polychromatic X-rays and a single crystal of large size rotated through a small angle about an axis lying in a crystal face.

bulb (in X-ray tubes)—The glass (or other pressure-tight) part; when of metal, more usually called the body.

calcite—Natural rhombohedral CaCO_3 , the primary standard crystal used in X-ray spectrometry.

cassette (in X-ray spectrographs)—A box for holding a photographic film or plate in position to receive the X-ray diffraction-pattern.

cell—See unit cell.

centered (concerning space-lattices)—Body-centered.

channel (in X-ray spectrographs)—A collimating system consisting of a hole through a thick piece of metal (usually in two parts to permit cleaning).

*Prof. of Physics and Director of Sloane Physics Laboratory, Yale University, New Haven, Conn.
¹"Proceedings," A.S.T.M., v. 26, pt. 1, p. 582, 1926.

chaotic—See orientation.

characteristic X-rays—Series of monochromatic X-rays which are emitted (in addition to heterochromatic X-radiation) by a particular element when exposed to cathode-rays (or X-rays) of sufficiently high energy.

close-packed (concerning atomic arrangement in crystals)—Having one of the two possible arrangements, one cubic and one hexagonal, in which equal hard spheres can be made to occupy the least total volume, and, by extension, having any of the hexagonal arrangements derived from the second of these by expansion or contraction of the hexagonal axis. See face-centered and hexagonal close-packed.

coefficient—See absorption coefficient, mass-absorption coefficient, mass-scattering coefficient

collimate—To isolate a parallel, or nearly parallel, beam of rays, as by slits, pinholes, or a channel

continuous spectrum—Heterochromatic X-rays.

Coolidge (concerning X-ray tubes)—Having a high vacuum and a hot-wire cathode.

covering-operation—A general name for translations, symmetry-operations, and their combinations in extended structures by which every element (point, line, and plane) of the structure is replaced by an equivalent element. Besides translations and symmetry-operations there are screw-rotations about screw-axes and glide-reflections in glide-reflection-planes.

critical (concerning voltage, wave length or frequency)—Limiting; see limit.

cross-direction (in rolled metal)—The direction parallel to the axes of the rolls during rolling

crystal (noun)—A coherent piece of matter all parts of which have the same anisotropic arrangement of atoms; in metals usually synonymous with grain and crystallite.

crystal (adjective)—Of, or pertaining to, crystals.

crystal analysis—The determination of crystal structure.

crystal unit—Unit of structure.

crystalline—Composed of crystals.

cubic-centered (concerning space-lattices)—Body-centered cubic

cubic (concerning crystals)—Having nonparallel 3-fold axes of symmetry, with other symmetry-elements. Sometimes called isometric or regular. The typical cubic crystal has three equivalent axes (2-fold or 4-fold) mutually perpendicular, and the common parameter is usually written a (or a_0).

dated (concerning X-ray diffraction-patterns from crystal aggregates)—Made up of separately distinguishable images of the source.

Debye-Scherrer method (for X-ray crystal analysis)—Using a monochromatic (or polychromatic) X-ray beam defined by pinholes, an aggregate of small crystals oriented more or less completely at random and a photographic film bent into an almost complete cylinder with its axis perpendicular to the X-ray beam at the crystalline specimen; practically indistinguishable from the Hull method; sometimes called the powder method.

define (X-rays)—To limit in angle, as by slits or pinholes; to collimate.

deviation (X-ray)—The angle between the direction of incidence (produced through the substance) and the direction of diffraction; twice the glancing angle of incidence; usually written 2θ .

diagram (for X-ray diffraction-patterns)—A representation, either a photograph as taken, or a projection therefrom; for example, the index-diagram.

diamond-cubic (concerning atomic arrangements)—Similar to the diamond in having two face-centered cubic arrangements of atom-centers either of which is displaced with respect to the other by one-fourth of the diagonal of the unit cube.

diffraction (X-ray)—The deviation of an X-ray beam by scattering from atoms which have some regularity of arrangement or spacing.

diffraction-pattern (X-ray)—The totality of the intersections, with a plane or other surface, of the beams diffracted by a crystal or by a crystalline aggregate.

discontinuity (in absorption)—The ratio between absorption coefficients at a limit.

doublet (in characteristic X-ray spectra)—A pair of lines from the same element which differ little in wave length; for example, the $K\alpha$ -doublet, $K\alpha_1$, and $K\alpha_2$.

electron X-ray tube—An X-ray tube in which the current is maintained by thermionic emission from a hot cathode. See Coolidge.

end-centered (concerning orthorhombic space-lattices)—Having equivalent points at the corners of the unit cell and at the centers of the pair of opposite faces perpendicular to the c -axis. Same as side-centered with a different choice of axes.

equivalent (concerning points, lines, planes, and atoms)—Being interchangeable by the covering-operations appropriate to the structure.

excite (X-rays)—To cause to be emitted.

exposure (to X-rays)—The time-integral of the intensity; with X-ray tubes of the same kind and operated under the same conditions the exposure is proportional to the product of the electron current through the tube by the time of operation.

face (crystal)—A natural surface, or a cut surface parallel to a possible natural surface.

face-centered (concerning cubic space lattices)—Having equivalent points at the corners of the unit cell and at the centers of its six faces. A face-centered cubic space-lattice is characteristic of one of the close-packed arrangements of equal hard spheres.

family (of crystal planes)—The planes in any one crystal which have common indices.

fiber-axis—See fibering.

fiber-diagram—An X-ray diffraction-pattern, or a chart prepared therefrom, showing the existence of fibering or measuring its completeness.

- fibering** (in crystalline aggregates)—The state of a crystalline aggregate in which the preferred orientations are obtained by rotation about a line, the fiber-axis. If fibering is complete all azimuths about the fiber-axis are equally probable. If fibering is incomplete the preferred orientations may reduce to a small number and the notion of fibering loses its value. Besides simple fibering there may be helical fibering in which the fiber axis has all the orientations assumed by the tangent to a helix of constant pitch. In ring-fibering the pitch of the helix is zero.
- filter** (for X-rays)—A sheet of matter selectively absorbing secondary or other undesired X-rays. See also balanced filters.
- fluorescent screen** (for X-rays)—A sheet of matter (usually mounted on paper or other non-absorbent material) which emits visible or actinic light when exposed to X-rays.
- fluorescent X-rays**—Characteristic X-rays excited by X-rays.
- focus** (in X-ray tubes)—The spot on the target where the cathode rays are concentrated and which is therefore the principal source of X-rays; its shape and size are controllable by design.
- focusing** (concerning methods of X-ray or crystal analysis)—Using such a shape and position of sample and position of source that the diffracted X-rays from many (or all) parts of the sample fall close together in the diffraction-pattern; such methods permit the use of wide beams and require relatively short exposures. See Bragg method and Seemann-Bohlin method.
- form** (for equivalent crystal planes or lines)—Having the same indices, except for sign or order, for example, the planes (110), (101) in a cubic crystal are both of the form {110}; the planes (110), (101) in a tetragonal crystal are not of the same form. The lines [210], [120], [012] in a cubic crystal are of the form $\langle 210 \rangle$.
- frequency** (X-ray)—Measured by the equation $\nu = c/\lambda$, wherein c is the velocity of propagation of light (3×10^{10} cm. per sec.) and λ is the wave length in centimeters.
- frequency-factor** (for crystal planes of a form)—The number of different families of planes having the same form.
- gas X-ray tube**—An X-ray tube in which the current is initiated by ionization of residual gas at a pressure of the order of 10^{-3} mm. of mercury. This gas pressure must be kept within narrow limits during operation.
- general** (concerning X-radiation)—Heterochromatic.
- glancing angle**—The angle between the incident X-ray beam and the crystal planes from which reflection takes place, however these may be inclined to the bounding surface of the crystal usually written θ .
- glide-reflection-plane**—See plane of symmetry.
- gnomonic projection**—A projection in which each plane of a crystal is represented by the point in which the perpendicular let fall upon it from a fixed point meets the plane of the projection.
- goniometer**—An instrument for measuring angles or for setting objects in known orientations. Spectrographs and spectrometers are goniometers of a special sort.
- grating-constant** (in crystals)—Interplanar distance.
- grating-space** (in crystals)—Interplanar distance.
- halo** (in X-ray diffraction patterns)—A diffuse circular band.
- hard** (concerning X-rays)—Having great penetrating power, short wave length, high frequency.
- hemihedral** (concerning crystals)—Having but one-half of the symmetry-elements possible to the crystal system in which the crystal belongs; having different properties in opposite directions, or on opposite faces, or lacking symmetrically opposite faces.
- heterochromatic** (concerning X-rays)—Having a continuous series of wave lengths, as from a tube operated below the critical voltage for its target.
- heterogeneous** (concerning X-rays)—Heterochromatic.
- hexagonal** (concerning crystals)—Having parallel 6-fold rotation-axes of symmetry, or a single set of parallel 3-fold rotation-axes of symmetry with planes of symmetry perpendicular thereto, and with or without other symmetry-elements. The typical hexagonal crystal has two equal axes $b = a$ inclined at the angle 120° and a third axis (c) perpendicular to their plane.
- hexagonal close-packed** (concerning atomic arrangements in crystals)—Having atoms at the corners of the hexagonal unit cells, which are right prisms with rhombic bases, and at the centers of those (isosceles) triangular prisms which are similarly located halves of the hexagonal unit cells. The two sets of atoms are not crystallographically equivalent. If the atoms are arranged like hard equal spheres in contact, $C = 1.633$ or $2\sqrt{3}/3$.
- holohedral** (concerning crystals)—Having all the symmetry-elements possible to the crystal system in which the crystal belongs.
- homogeneous** (concerning matter)—Having the same properties in every small region containing many atoms (but not necessarily isotropic).
- homogeneous** (concerning X-rays)—Monochromatic.
- Hull method** (for X-ray crystal analysis)—Using a monochromatic (or polychromatic) X-ray beam defined by slits (or pinholes), an aggregate of small crystals oriented more or less completely at random and a photographic plate or a photographic film (if the latter, bent around a cylinder with its axis perpendicular to the X-ray beam at the crystalline specimen); practically indistinguishable from the Debye-Scherrer method; sometimes called the powder method.
- identity-period** (along a crystal line)—A primitive translation.
- image** (in X-ray diffraction-patterns)—By analogy with optics, a recognizable copy of the source of X-rays or of any aperture defining the X-ray beam.
- index-diagram**—A chart based upon an X-ray diffraction-pattern and permitting the assignment of indices to the families of planes responsible for the intensity maxima in the pattern.
- indices**—See Miller indices, Miller-Bravais indices, line-indices.

- intensifier** (for X-rays)—A substance placed in, on, or under a photographic emulsion or a fluorescent screen, or used in photographic development, to make the effects of X-rays more conspicuous.
- intensifying factor** (for X-ray intensifiers)—The ratio between the exposure when no intensifier is used to the exposure, for the same effect, when the intensifier is used, all other conditions remaining unaltered.
- intensifying screen** (in X-ray spectrographs)—A separately mounted intensifier.
- intensity** (X-rays)—The flux of energy per unit of time and per unit of cross-section perpendicular to the direction of propagation.
- interplanar distance** (in crystals)—The perpendicular distance between the nearest equivalent planes of a family; usually written d . The indices of the planes may be written as a subscript, for example, d_{100} .
- inversion**—A symmetry operation by which each point of a structure is replaced by a point at the same distance from a fixed point (the inversion-center) but in the opposite direction therefrom. See also symmetry-operation.
- ionization method**—Any method of X-ray or crystal analysis which depends upon measuring the electrical conductivity of a gas exposed to the diffracted X-rays; great accuracy in angular measurement is possible, but not easy.
- isometric** (concerning crystals)—Cubic.
- isotropic**—Having the same properties in every direction.
- K**—The letter used to designate the series of characteristic X-rays having, for each element, the shortest wave lengths; Greek letters and Arabic subscripts are used to distinguish the lines of the K-series; for example copper $K\alpha$, molybdenum $K\beta$, L and M are used to designate characteristic groups of X-rays of successively greater wave length, but these are rarely used in crystal analysis.
- lattice**—Space-lattice. Lattice-lines and lattice-planes are lines and planes so chosen as to pass through more than one lattice-point, and noncollinear lattice-points respectively.
- Laue method** (for crystal analysis)—Using heterochromatic X-rays, a small fixed crystal and a plane screen, usually a photographic plate; the Laue spot is the image (of a pinhole or of the small crystal itself) characteristic of the resulting diffraction-pattern.
- layer-line** (in revolving-crystal and oscillating-crystal methods)—A row of spots due to families of planes equally inclined to the axis of rotation or oscillation. Compare with side spectrum, zero spectrum.
- limit** (in voltage, wave length or frequency of X-rays)—A value, characteristic of the particular chemical element in question, on the two sides of which excitation, absorption, photographic effect, or the like, have sharply different values.
- line** (crystal)—A possible edge of a crystal.
- line** (in X-ray diffraction-patterns)—A straight or slightly curved narrow region of maximal intensity.
- line** (X-ray)—A group of monochromatic X-rays, not necessarily collimated.
- line-focus** (in X-ray tubes)—A focus with one dimension reduced to such an extent that the focus approximates to a segment of a straight line on the target in the plane determined by the axis of the tube and the direction from the target to the irradiated object. (This secures the advantages of a point source of X-rays without extreme local heating).
- line-indices**—The smallest integers proportional to the coordinate-differences, in terms of the parameters (a , b , and c), between equivalent points lying on a crystal line; written, in general [HKL], in particular, for example [210]; in cubic crystals the line $[pqr]$ is perpendicular to the plane (pqr) .
- mass-absorption coefficient** (for X-rays in a substance)—The rate of decrease, per unit mass traversed, of the natural logarithm of the intensity of a parallel beam; usually written μ/ρ . It is often more convenient than the absorption-coefficient because its use does not require knowledge of the density ρ . See also mass-scattering coefficient.
- mass-scattering coefficient** (for X-rays in a substance)—The rate of decrease, per unit mass traversed, of the natural logarithm of the intensity of a parallel beam, due to scattering alone; usually written σ/ρ ; the excess of the mass-absorption coefficient, μ/ρ , over σ/ρ is called the true mass-absorption coefficient, μ'/ρ .
- Miller indices** (for crystal planes)—The smallest integers proportional to the reciprocals of the intercepts, in terms of the parameters (a , b , and c), of the plane on the three crystal axes; written, in general, (hkl) , in particular, for example (210); see also form.
- Miller-Bravais indices** (for crystal planes in the hexagonal division of the hexagonal system only)—The smallest integers proportional to the reciprocals of the intercepts, in terms of the parameters (a , a , a , and c), of the plane on the four axes; written, in general (hkl) , in particular, for example (1120); the index for the hexagonal axis is always written last; $k = -(h + l)$ and may be replaced by a period, thus (1120) and (11.0) are the same. Any two of the three equivalent axes 120° apart in the basal plane together with the fourth axis are crystallographically sufficient, but the use of four axes makes it easier to recognize planes of the same form.
- monochromatic** (concerning X-rays)—Having only a single wave length.
- monoclinic** (concerning crystals)—Having only parallel 2-fold axes of symmetry, or parallel planes of symmetry, or both of these with the axes perpendicular to the planes. The typical monoclinic crystal has three unequal axes, only one of which is perpendicular to two others. The unique axis is usually taken as the b -axis.
- multiplicity** (for axes of symmetry)—The value of N if the axis is N -fold.

- order** (in X-ray reflection)—The integral value of n in the equation $n\lambda = 2d \sin \theta$.
- orientation** (crystal)—Arrangement in space of the axes of a crystal; every crystal must at every moment have a definite orientation, only aggregates, in space or in time, can possess chaotic orientation; if not chaotic some one or more orientations must be preferred.
- orthohexagonal** (concerning crystal axes)—A set of mutually perpendicular axes for hexagonal crystals. In terms of the more usual hexagonal parameters (a , a , c) the orthohexagonal parameters are $a\sqrt{3}$, a , c .
- orthorhombic** (concerning crystals)—Having only parallel 2-fold axes of symmetry, with planes of symmetry parallel to the axes or with additional 2-fold axes perpendicular thereto, or with both. The typical orthorhombic crystal has three unequal axes mutually perpendicular.
- oscillating-crystal method** (for X-ray or crystal analysis)—Using a single crystal rotating at constant speed, but alternately in both directions, through less than a complete rotation (usually much less).
- parameter** (in crystals)—A characteristic magnitude defining the unit cell or the position of a point within it. The edges of the unit cell, a , b , c , and the angles, α (between b and c), β (between c and a), γ (between a and b), are its parameters. The edge of the unit cube, a_0 , is the single parameter of a cubic lattice. When the fractional co-ordinates of a point within the unit cell may vary the values of these fractions: x , y , z , are parameters of the structure.
- pattern**—Diffraction-pattern.
- photogoniometer**—An X-ray goniometer with photographic registration.
- pinhole**—A small round hole used to define a beam of X-rays.
- plane** (crystal)—A possible face of a crystal.
- plane of symmetry**—A plane in a crystal in which a reflection, with or without a translation parallel to the plane, replaces every element (point, line, and plane) of the crystal by an equivalent element. The plane is a reflection-plane if no translation is involved, and is a glide-reflection plane if translation is involved.
- point-group**—A limited group of points (from 1 to 48 in number) possessing the same symmetry-elements as one of the 32 possible classes of crystals.
- pole-figure** (for crystalline aggregates)—A stereoscopic projection showing the preferred orientations of the normals to planes of a given form.
- polychromatic**—Having several distinct wave lengths, for example, the characteristic X-rays from a single element.
- powder method** (for X-ray or crystal analysis)—Using a loose aggregate of small crystals with chaotic orientation; applied, early but somewhat illogically, to methods using solid metals composed of crystalline aggregates; see Debye-Scherrer method, Hull method.
- preferred**—See orientation.
- primary** (concerning X-rays)—Emitted directly from the anticathode in the X-ray tube.
- primitive**—See translation.
- principal spectrum** (in revolving-crystal and oscillating-crystal patterns)—Zero spectrum.
- pseudocrystalline**—Possessing regularities of structure which result in a diffraction-pattern unlike that of a liquid or an amorphous solid, although true crystals are not present, for example, stretched rubber is pseudocrystalline.
- radiography**—The use of X-rays in studying the macrostructure of single objects or assemblies (internal boundaries, inclusions, variations in density or composition).
- random** (concerning orientation)—Chaotic.
- rating** (for X-ray tubes)—The product of the allowable current by the (peak) operating voltage.
- ratio**—See axial ratio.
- reciprocal lattice** (for a crystal)—A group of points so arranged about a center that the line joining each point to the center is perpendicular to a family of planes in the crystal, and its length is inversely proportional to their interplanar distance.
- reflection** (X-ray)—Diffraction considered as due to scattering by crystal planes as units, these being the reflecting planes; monochromatic X-rays are reflected only when $n\lambda = 2d \sin \theta$, where n is order, λ wave length, d , interplanar distance, and θ , glancing angle of incidence upon the planes considered.
- reflection-plane**—See plane of symmetry.
- regular** (concerning crystals)—Cubic.
- revolving-crystal method** (for crystal analysis)—Using a small single crystal rotating uniformly through many complete rotations during the time of the exposure.
- rhombohedral** (concerning crystals)—Having parallel 6-fold rotatory-reflection-axes, or a single set of parallel 3-fold rotation-axes, in either case without planes of symmetry perpendicular thereto, and with or without other symmetry-elements. The typical rhombohedral crystal has three equal axes ($c = a$, $b = a$) mutually inclined at an angle α not usually equal to 90° .
- rock salt**—Natural (cubic) NaCl, the secondary standard crystal used in X-ray spectrometry.
- rolling-direction** (in rolled metal)—The direction, in the plane of the sheet, perpendicular to the axes of the rolls during rolling.
- rotation-axis**—See axis of symmetry.
- rotation-diagram**—A chart used in assigning indices to families of planes giving spots in the diffraction-patterns obtained in revolving-crystal or oscillating-crystal methods for crystal analysis.
- rotatory-reflection-axis**—See axis of symmetry.
- scattering** (X-ray)—The re-emission of X-rays from irradiated matter, without change of wave-length (except as modified by the Compton effect, which is negligible in crystal analysis); it takes place in all directions with respect to the incident X-rays, but more intensely (or more often) in some directions than in others.

- screen** (in X-ray spectrographs)—A flat or curved surface on which a diffraction-pattern may be observed, for example, a fluorescent screen; sometimes, but not so properly, a shield.
- screw-axis**—See axis of symmetry.
- secondary** (concerning X-rays)—Emitted elsewhere than from the anticathode.
- secondary spectrum** (in revolving-crystal and oscillating-crystal patterns)—Side spectrum.
- Seemann-Bohlin method** (for crystal analysis)—Using a monochromatic (or polychromatic) X-ray beam of wide angular aperture, an aggregate of small crystals oriented more or less completely at random and spread on a cylinder an element of which also passes along the single slit defining the X-ray beam, and a photographic film bent to fit another segment of the same cylinder; it is a focusing method.
- series** (in X-ray spectra)—A group of characteristic X-rays having the same excitation-limit, distinguished as K-series and L-series. See also K.
- shield** (in X-ray spectrographs)—A plate, block, or the like, which prevents X-rays (usually secondary) from reaching the measuring or detecting device; a complete absorber.
- shutter** (in X-ray spectrographs)—A removable shield.
- side-centered** (concerning orthorhombic space-lattices)—Having equivalent points at the corners of the unit cell, and at the centers of the pairs of opposite faces perpendicular to the a-axis and to the b-axis. Same as end-centered with a different choice of axes.
- side spectrum** (in revolving-crystal and oscillating-crystal patterns)—A row of spots due to planes equally inclined to the axis of rotation or oscillation, but not parallel thereto. Compare with layer-line, zero spectrum.
- simple** (concerning space-lattices)—Having equivalent points only at the corners of the unit cell.
- slit**—A narrow opening with parallel sides, used to define a beam.
- slit-system**—A series of slits used to define a beam and to shield against secondary X-rays.
- slitless spectrograph**—Wedge-spectrograph.
- soft** (concerning X-rays)—Having little penetrating power, long wave length, low frequency
- source** (X-ray)—See focus.
- space-centered** (concerning space-lattices)—Body-centered.
- space-group**—An infinitely extended group of points possessing the same symmetry-elements and the same translations as one of the 230 different arrangements theoretically possible for atoms in crystals. The great number of space-groups as compared with point-groups is due to the fact that a different location in space for the same symmetry-elements is possible in the space-group but not in the point-group.
- space-lattice** (crystal)—A system of equivalent points formed by the intersections of three sets of planes parallel to pairs of principal axes; the space-lattice may be thought of as formed by the corners of the unit cells. See translation-group
- spacing** (between crystal planes)—Interplanar distance.
- spectrograph** (X-ray)—An instrument using an extended surface—a photographic plate or film, or a fluorescent screen—for receiving the X-ray diffraction-pattern
- spectrometer** (X-ray)—An instrument using a movable measuring device for exploring the X-ray diffraction-pattern.
- spectrum** (X-ray)—A distribution of X-rays along a line in accordance with wave length, or a group of X-rays so distributable. The set of layer-lines furnished by the revolving-crystal method is sometimes called the complete spectrum. See also side spectrum, zero spectrum
- stereographic projection**—A projection in which each plane of a crystal is represented by the point in which a perpendicular let fall upon it from a fixed point meets a sphere centered at the fixed point, and these representative points on the sphere are then represented in turn by the points in which lines drawn to them from the pole of a great circle of the sphere meet the diametral plane through the great circle.
- structure**—The arrangement of parts; especially, in crystals, the shape and dimensions of the unit cell and the number, kinds and positions of the atoms within it.
- symmetry**—See axis of symmetry, inversion, plane of symmetry.
- symmetry-element**—A general name for axes of symmetry, planes of symmetry and centers of inversion.
- symmetry-operation**—A geometrical operation which interchanges equivalent elements (points, lines, and planes) of a rigid geometrical figure. The possible symmetry-operations are rotations about rotation-axes passing through the center of the figure and reflections in reflection-planes passing through the same point. A rotary-reflection is a compound operation in which the rotation-axis must be perpendicular to the reflection-plane. An inversion is equivalent to a 2-fold rotatory-reflection about any rotatory-reflection-axis.
- system** (crystal)—One of the 6 classes into which the 32 possible types of crystal and the 230 possible types of structure have been divided on the basis of symmetry. They are triclinic, monoclinic, orthorhombic, tetragonal, hexagonal (including rhombohedral and hexagonal divisions), and cubic.
- target** (in X-ray tubes)—The part of the anticathode, wholly or predominantly of a single metal, or coated with a substance to be analyzed, where the focus lies.
- tetartohedral** (concerning crystals)—Having but one-fourth of the symmetry-elements possible to the crystal system in which the crystal belongs.
- tetragonal** (concerning crystals)—Having parallel 4-fold axes of symmetry but no 3-fold axes of symmetry. The typical tetragonal crystal has two equal axes ($b = a$) perpendicular to each other and to a third axis (c).
- translation** (in a crystal or space-group)—A displacement parallel to a crystal line. A primitive translation is the least translation, without accompanying rotation or reflection, which replaces every element (point, line, and plane) by an equivalent element. Suitable fractional parts of

- a primitive translation may be combined with rotation or reflection in screw-rotations and glide-reflections.
- translation-group**—An infinitely extended group of points possessing the same translations as one of the 14 possible space-lattices in crystals.
- transmission method** (for X-ray or crystal analysis)—Having the diffracted X-rays emergent from a surface which does not face the source.
- triline** (concerning crystals)—Having no symmetry-elements, or only inversion-centers. The typical triclinic crystal has three unequal axes no two of which are perpendicular.
- uniform** (concerning X-ray diffraction-patterns)—Not dashed.
- unit cell** (in crystals)—The least parallelepiped which possesses the full symmetry of the crystal, and repetition of which without change of orientation builds up a crystal of any size.
- unit cube** (in crystals)—The unit cell in cubic crystals.
- unit of structure** (in crystals)—The group of atoms included by the unit cell, especially if the arrangement of the group indicates chemical relations between its members.
- wave length** (X-ray)—The value of λ in the equation, $\lambda = \frac{2d \sin \theta}{n}$; wherein d is the interplanar distance in a crystal which reflects the X-rays at the glancing angle θ in the n th order.
- wedge-spectrograph**—An X-ray spectrograph (due to Seemann) in which the beams of incident and diffracted X-rays are limited by a wedge brought into contact with a face of the crystal; also called slitless spectrograph.
- Weissenberg photogoniometer**—A photogoniometer with a cylindrical film so shielded and axially advanced during exposure that the spots of a single layer line are consecutively recorded along its direction of travel.
- white** (concerning X-rays)—Heterochromatic.
- X** (abbreviation)—X-unit, 10^{-11} cm.; also written X.U.
- X-radiation**—X-rays in general, especially when their direction of propagation is not emphasized.
- X-ray** (adjective)—Of or pertaining to X-rays.
- X-ray analysis**—The measurement of X-ray wave lengths and intensities
- X-ray tube**—An assembly of cathode, anticathode, and bulb (or body) suitable for the production X-rays.
- X-rays**—Light-rays, excited usually by the impact of cathode-rays on matter, which have wave lengths between about 10^{-6} cm., and 10^{-9} cm.; also written x-rays; same as Röntgen-rays.
- zero spectrum** (in revolving-crystal and oscillating-crystal patterns)—A row of spots due to planes parallel to the axis of rotation or oscillation. Sometimes called zero line. Compare with layer-line, side spectrum.
- zone-axis** (in a crystal)—A line parallel to several crystal planes; the planes to which it is parallel form its zone

German Terms with English Equivalents

This list contains principally those German terms likely to be mistranslated. Many of the short words here given will usually be found in combination. Such combinations are only included if their proper translations cannot be derived from the translations for their parts. It must be understood that the translations given are to be preferred only when the term is used in its technical sense. In non-technical uses other equivalents will often be better.

- | | |
|---|---|
| Ablenkungswinkel—deviation | Lagerung—orientation. |
| Absorptionssprung—absorption-discontinuity | Leuchtschirm—fluorescent-screen. |

| Grobstruktur—coarse structure, as may be revealed by radiography. | Zähligkeit—multiplicity. |
| Häufigkeitsfaktor—frequency-factor. | Zerstreuung—scattering. |
| Hauptspektrum—principal spectrum. | |

Tool Steel Trade Names

The manufacturer's and the trade names of tool steels with the approximate composition of the important alloying elements are given in the following compilation. The firms are arranged alphabetically and then numbered.

If the trade name is known but not the manufacturer, this can be ascertained by referring to the second section which gives the trade names alphabetically arranged and each name preceded by the firm's number which corresponds with the listing in the first section.

Manufacturers are indicated by the superior ^a, the dealers by ^b, and importers by ^c.

TRADE NAMES OF TOOL STEELS

(Alphabetically Arranged)

The number preceding each trade name indicates the firms listed in the first section of this compilation. The approximate composition of the important alloying elements is also given with the trade name and the firms.

A			B			C		
17. A-B-O			6. Best Carbon			13. Columbia Double Special		
4. A-C-T H.S.			41. Bit Steel			45. Columbia Double Special

Trade Names of Corrosion and Heat Resisting Alloys

(Iron, Chromium, or Nickel Base Alloys)

The manufacturers and the trade names of the corrosion and heat resisting alloys of iron, nickel, or chromium base types are given in this compilation together with the approximate composition of the important alloying elements. The manufacturers are arranged alphabetically and then numbered.

If the trade name is known but not the manufacturer, this can be ascertained by referring to the second section which gives the trade names alphabetically arranged and each name preceded by the manufacturer's number which corresponds with the listing in the first section.

Trade Names of Corrosion and Heat Resisting Alloys

(Alphabetically Arranged)

The number preceding each trade name indicates the manufacturer listed in the first section of this compilation. The approximate composition of the important alloying elements is also given with the trade name under the manufacturer.

<p>A</p> <p>44. A Nickel</p> <p>22. A R. Stainless</p> <p>67. Acid Resisting Shawinigan KA-2 and KA-2-Mo</p> <p>3. Acme</p> <p>1. Acme Stainless Type 410, 430, 301-X, 302, 304</p> <p>74. Weights of Steel Bars

Carbon Steels—Approximate weights of carbon steel bars in rounds, squares, hexagons, octagons, and flats are given in the following tables. The weights given have been calculated from the unit, 1 cu. in. equals 0.2833 lb. or its equivalent, 1 cu. ft. equals 489.54 lb. A convenient unit much used in practice is 1 cu. in. equals 0.3 lb. This gives weights about 6% heavier than those in the tables, but since bar steel is usually furnished slightly full to size, weights calculated on this basis yield fairly close working results for all except very large sizes.

High Speed Steels—On account of the large proportion of special elements present, high speed steels are heavier than carbon steels. While this increased weight is not constant, a fairly close estimation of the weight of high speed steels may be obtained by adding 10% to the figures for carbon steels as given in the tables. In other words, multiply the figures in the tables by 1.1 to obtain the weight of high speed steel.

Useful Methods for Calculating Weights—There are several methods which may often be used to advantage in determining weights of odd-sized bars not included in the subsequent tables.

(1) To find the weight per ft. of any size round, square or octagon, square the diameter (or stated dimension) and multiply by the weight per ft. of 1 in. round, square or octagon, respectively.

(2) The weight per ft. of octagon steel may be found by multiplying the weight per ft. of a round bar of the same size by 1.0547.

(3) The weight per ft. of hexagon steel may be found by multiplying the weight per ft. of a round bar of the same size by 1.1026.

(4) To find the weight per ft. of any flat, multiply the product of the width and thickness by the weight per ft. of 1 in. sq.

Temperature Conversion Data

The two temperature scales commonly used in metallurgical work are Fahrenheit and Centigrade. In the former the freezing of water is called 32° and its boiling point 212°; in the latter the freezing temperature of water is taken as 0° and the boiling point 100°. Thus 100 divisions (100-0) on the Centigrade scale are equivalent to 180 divisions (212-32) on the Fahrenheit scale or one Centigrade degree is 9/5 (180/100) of a Fahrenheit degree. Conversion from one scale to the other may be made quite readily by the following formulae based on the relations given above.

(a) Conversion from Fahrenheit (F.) to Centigrade (C.) : $C = 5/9 (F.-32)$.

(b) Conversion from Centigrade (C.) to Fahrenheit (F.) = $9/5 (C.) + 32$.

Problem—How many °F. are equivalent to 355°C.?

How many °C. are equivalent to 1505°F.?

In the first case use formula (b) which becomes

$$F = 9/5 (355) + 32 = 639 + 32 = 671$$

In the second case use formula (a) which becomes

$$C = 5/9 (1505-32) = 5/9 (1473) = 818.33$$

Temperature Conversion Table—Many tables and charts have been prepared for direct conversion from one temperature scale to the other, but they are, of necessity, quite large if direct readings to the nearest degree are given. A most useful small table¹ from which accurate conversions can be obtained is given on the next page. It will be noted that all Centigrade readings are given in heavy type; the figures in light type are Fahrenheit readings. The table gives direct readings at even 10°C. intervals from -270-3990°C. Conversions to the nearest degree are made by means of the "Interpolation Columns" at the right side of the page.

For example, to convert 355°C. to the Fahrenheit scale follow horizontally to the right from 300°C. in column 1 until under 50. The reading here is 662 and represents the equivalent in degrees Fahrenheit of 350°C. To find the equivalent of 355°C. which is 5°C. higher than the value we now have, obtain the Fahrenheit equivalent of 5°C. from the "Interpolation Column" at the upper right side of the page; this is 9°F. Add to 662°F., which gives 671°F. as the equivalent of 355°C.

Likewise, to find the equivalent on the Centigrade scale of 1505°F., locate the nearest number to this in the body of the main table. This is 1508°F. in the fourth column under the heading 20 and opposite 800. In other words, 1508°F. is equivalent to 820°C. The equivalent of 1505°F., or three degrees less, may be found by subtracting the equivalent of 3°F. (= 1.67°C.), obtained from the "Interpolation Column" at the lower right-hand side of the sheet, from 820°C. Thus 1505°F. equals 818.33°C.

¹Based on data prepared by Dr. Leonard Waldo, Metallurgical and Chemical Engineering.

Specific Heat of Gases

By J. H. G. Williams*

Air is a mechanical mixture of chemical elements and compounds, as follows: Oxygen, nitrogen, carbon dioxide, water vapor, traces of dust, and rare gases. Dry air is free of water vapor.

Saturated air contains the maximum amount of water vapor possible at any particular temperature and barometric pressure.

Atmospheric air usually contains an amount of moisture (water vapor) less than saturated air. The amount of moisture in atmospheric air relative to the amount of moisture in saturated air (humidity) is reported daily by the U. S. Weather Bureau, as well as the mean temperature and the barometric pressure.

Variations in the amount of moisture modify the specific heat of air, and, therefore, the specific heat of dry air at a given temperature should be corrected for the actual humidity condition.

The weight in lb. per cu. ft. of moist air is represented by the equation:

$$(a) \quad D = 1.326 \left\{ \frac{B}{T} \right\} - 0.501 \left\{ \frac{he}{T} \right\}$$

where

D = weight in lb. per cu. ft. of moist air at temperature T and relative humidity h

t = temperature of the air in °F.

T = absolute temperature = $t + 459.6$

B = barometric pressure in in. of mercury

h = relative humidity

e = pressure of saturated vapor corresponding to temperature t , in in. of mercury.

Problem—On July 6, 1923, the report of the U. S. Weather Bureau for Hartford at 8:00 a. m., was

Barometer 30; temperature 66, and humidity 92.

What was the specific heat of the air at 1500°F.?

Solution of Problem—The term $1.326/T$ in equation (a) can be obtained directly from Table II by dividing the figures given in column 6 by 1000. For 66°F. this equals 0.002523.

Likewise the term $0.501 e/T$ can be obtained from Table II by dividing the figures given in column 7 by 1000. For 66°F. this equals 0.000614.

Substituting in equation (a) we have:

$$D = 0.002523 \times 30 - 0.000614 \times 0.92 = 0.0751 \text{ lb. per cu. ft.}$$

This air consists of water vapor and dry air.

To find the weight of water vapor in the air, multiply the (relative) humidity by the weight of 1 cu. ft. of completely saturated vapor at the stated temperature (66°F.), as shown in Table I, and divide by 100, thus:

Pounds of water vapor per cu. ft. of air =

$$\frac{0.1001 \times 0.92}{100} = 0.0009$$

Now, we have

$$0.0751 - 0.0009 = 0.0742 \text{ lb. of dry air, and} \\ 0.0009 \text{ lb. of water vapor}$$

in our mixture at 66°F. Hence 1 lb. of the mixture should consist of:

*Metallurgical Engineer, The Hartford Electric Steel Corp., Hartford, Conn.

$$\frac{0.0742}{0.0751} \times 100 = 98.8\% \text{ dry air, and}$$

$$\frac{0.0009}{0.0751} \times 100 = 1.2\% \text{ water vapor}$$

The mean specific heat of air with any degree of saturation may be found by multiplying the weight of dry air by its specific heat and adding the product of the weight of water vapor by its specific heat and then dividing the sum by the total weight.

The mean specific heat of dry air at any temperature "t" is shown in column 3, Table III, to be equal to

$$0.240 + 0.0000051 \text{ t}$$

Likewise the mean specific heat of water vapor at any temperature "t" is shown to be equal to

$$0.459 + 0.000031 \text{ t}$$

Thus the specific heat at 1500°F. for

$$\text{dry air is } 0.240 + 0.0000051 \times 1500 = 0.2477$$

$$\text{water vapor is } 0.459 + 0.000031 \times 1500 = 0.5055$$

Since there are 98.8 parts of dry air and 1.2 parts of water vapor per 100 parts of moist air, the total mean specific heat of the mixture is equal to

$$\frac{0.2477 \times 98.8}{100} + \frac{0.5055 \times 1.2}{100} = 0.2508 + 0.0069 = 0.2577$$

The Crystal Structure of Metals and Alloys*

By Kent R. Van Horn†

The various elements crystallize according to a definite pattern or symmetrical arrangement of atoms that is repeated at regular intervals to form a section of any size. The three dimensional lattice-work of imaginary lines connecting the atoms is called a space lattice. The smallest parallelepiped which possesses the full symmetry of the crystal is termed the unit cell. The type and dimensions of the unit cells of most elements have been determined and tabulated in X-ray books^{1, 2, 3, 4, 5} or summarized on page 78.

There are only 14 types of space lattices possible and they fall into the seven crystal systems, cubic, tetragonal, hexagonal, rhombohedral, orthorhombic, monoclinic and triclinic. The crystal systems are defined in the Glossary of X-ray terms on page 11. The large majority of the metals crystallize according to three of the fourteen space lattices, the face-centered and body-centered of the cubic

Periodic table showing chemical elements with crystal structures of high symmetry. The table is organized into groups I through VIII at the top. Elements are grouped by crystal structure: Hexagonal Close-Packed (HCP), Body-Centered Cubic (BCC), and Face-Centered Cubic (FCC). The table includes atomic numbers and element symbols.

Fig. 1—Periodic table showing the chemical elements having crystal structures of high symmetry.

system and the close-packed type of the hexagonal system. These three space lattices will be described in detail.

A periodic table of the elements is reproduced in Fig. 1 with the inert gases, and the metals beryllium and magnesium appearing twice to complete the symmetry of the arrangement. The number in the periodic system is indicated above each member of Group I and above the last element occurring on any horizontal line. The numerous elements crystallizing in the face-centered cubic, body-centered cubic, and hexagonal close-packed lattices are enclosed by characteristic markings. All polymorphic modifications having any of these three simple atomic arrangements are indicated by additional outlines (Fe, Co, Ti, etc.). The complex structures are not given. The majority of the metals which generally have one (or more when there are polymorphic modifications) of the three lattices of high symmetry appear at the left and the central part of the table. The nonmetallic elements, excepting the inert gases of Group VIII, are located at the extreme right of the table and have more complicated unit cells.

Since a high degree of crystalline symmetry, for example, face-centered cubic, body-centered cubic, and hexagonal close-packed arrangements, imparts the degree

*Revised section of the paper on "The Constitution of Alloys" by Kent R. Van Horn from the Symposium on Radiography and X-Ray Diffraction Methods, A.S.T.M., 1937.

†Aluminum Research Laboratories, Aluminum Co. of America, Cleveland.

of plasticity and other important properties enjoyed by metals, these typical structures will be briefly described. The plasticity of metals is generally attributed to movements in certain directions along specific crystallographic planes, all the atoms in one series of planes moving as a block relative to a similar series of parallel planes. The planes of easiest slip generally possess the greatest atomic concentration and the associated characteristic of a large distance between the intervening planes (interplanar distance). The latter feature implies that the restraining forces acting between consecutive planes will be a minimum. Also, slip within the favorite planes proceeds most easily along the atomic rows of highest density. It is the flowing or

gliding movement along these planes of atoms in specific directions which permits a solid metal to alter its external form. The three lattices of high atomic symmetry have more densely populated planes and lines of atoms than the complex structures. The three simple atomic arrangements also exhibit different degrees of plasticity, for example, metals crystallizing in the hexagonal close-packed system are generally less ductile than those of the face-centered cubic lattice.

Face-Centered Cubic Structure—

A more concrete picture of the familiar metal structures may be obtained from Fig. 2, 3 and 4 which were reproduced from Hume-Rothery's interesting treatise on alloys.* Fig. 2(a) shows the face-centered cubic unit cell with an atom located in each corner and center of each face of the cube. Fig. 2(b) illustrates the same configuration repeated for a number of cells but the atoms are represented by spheres in contact. This type of lattice is termed "close-packed" because the most intimate possible association of the spheres results. Although Fig. 2(b) more nearly typifies the manner

Fig. 2—Face-centered cubic structure. (a) Face-centered cubic unit cell. (b), (c), (d) Face-centered cubic packing of spheres in contact* (e) X-ray photograph of face-centered cubic copper. Mo-K α radiation.

in which the atoms exist in metals compared to the voids suggested by Fig. 2(a), it should not be inferred that an atom is a hard ball of specific dimensions. If the atom marked with a dot is removed from a corner of a cube of Fig. 2(b), the arrangement of Fig. 2(c) is obtained, exposing a plane of six spheres (appearing lighter in the illustration), lines through the centers of which form equilateral triangles. Fig. 2(d) shows the arrangement on this plane more clearly after the above six spheres are extracted. The same operation could be initiated from any of the corners of a cube, thereby uncovering eight similar close-packed planes in which each atom is at the center of a hexagon formed by lines through the centers of its six equidistant neighbors. The eight planes would form the faces of an octahedron if extended and are called the octahedral or $\{111\}$ planes.* There are only four series of $\{111\}$ planes as the opposite faces of the octahedron are parallel. The three rows of close atom packing on the $\{111\}$ planes are the sides of the equilateral triangles or $[110]$ directions which are the normals to the faces of the regular dodecahedron. The face-centered cubic lattice has, therefore, four close-packed planes $\{111\}$ and twelve close-packed directions $[110]$ which is the highest degree of atomic concentration and symmetry encountered in any crystal structure. Consequently, the metals of this type such as aluminum, copper, and silver are ductile, easily deformed, and are good conductors of heat or electricity. The X-ray pattern characteristics of this space lattice is included as Fig. 2(e).

Body-Centered Cubic Structure—The body-centered cubic unit cell has an atom at each corner and one in the center of the cube as illustrated in Fig. 3(a) and

* $\{111\}$ denotes the Miller indices which are the symbols of a crystallographic system for identifying the planes in space. (See page 14.)

represented by spheres in contact in Fig. 3(b).⁶ The low concentration of atoms, compared to Fig. 2(b), suggests that this structure is not one of most intimate atomic association. If the two spheres (marked by dots) of the nearest cube edge of Fig. 3(b) are removed, the result is shown in Fig. 3(c). The plane exposed is that containing the most atoms for this space lattice, namely, the cube diagonal or dodecahedral $\{110\}$ of which there are six sets. The large voids or interstices between the atoms signify that this plane is not one of close-packing compared to the face-centered cubic $\{111\}$ planes. Therefore, the body-centered cubic metals do not have a well defined slip plane but may deform by movement along various planes $\{110\}$, $\{112\}$, $\{123\}$ dependent on the relations of stress and the important directions $[111]$. Fig. 3(c) exhibits close-packed lines of atoms, the diagonal $[111]$ rows, which are normal to the four sets of octahedral $\{111\}$ planes. This condition

Fig. 3—Body-centered cubic structure. (a) Body-centered cubic unit cell. (b), (c) Body-centered cubic packing of spheres in contact.⁶ (d) X-ray photograph of body-centered cubic iron. MoK α radiation.

(no close-packed planes and only four close-packed directions) does not impart a high degree of plasticity⁷ and the metals of this class such as alpha iron, molybdenum, or tungsten, have great strength, high melting points and medium ductility. The X-ray pattern characteristic of this structure is illustrated in Fig. 3(d).

Hexagonal Close-Packed Structure—The close-packed hexagonal unit cell is depicted in Fig. 4(a) which is redrawn according to the conventional spheres in contact in Fig. 4(b). The close-packed arrangement approaches that of Fig. 2(b). The lower and upper horizontal planes of spheres exhibit the hexagonal grouping of one atom intimately surrounded by six neighbors. These planes of high atomic concentration are the basal faces $\{0001\}$ and the lines of close-packing on these planes are parallel to the edges of the first order prism faces $\{1010\}$. As the opposite faces of the hexagon are parallel, there is one close packed series of planes $\{0001\}$ and three important rows $[1010]$. Consequently it is to be expected that slip may proceed along specific planes in certain directions in this structure but not with the freedom of the face-centered cubic lattice (four planes, twelve directions). The hexagonal elements such as cadmium, magnesium, or zinc may accommodate their structure to stress by another mechanism, twinning, which alteration generates new additional slip planes $\{0001\}$ thereby approximating the plasticity characteristic of face-centered cubic metals and surpassing that of the body-centered cubic metals. The X-ray pattern characteristic of the close-packed hexagonal cell is represented in Fig. 4(c). Elements crystallizing with lower symmetry than the face-centered cubic, body-centered cubic, and hexagonal close-packed arrangements such as orthorhombic, monoclinic, or triclinic do not possess the close-packed planes and directions of slip or deformation. They are therefore relatively brittle and are not used as extensively as the more plastic metals.

Polymorphic Modifications of Metals—When a mineral or chemical compound crystallizes in two or more different forms, it is called polymorphic. Frequently the prefixes "di" or "tri" are used to denote the number of modifications if there are two or three. Metals which occur in two or more forms characterized by either different crystal structures or marked differences in energy content or both are generally called allotropic. The terminology has been the source of confusion as allotropy has been interpreted by some to represent a reversible change of a physical property

while others consider allotropy to be equivalent to polymorphism involving only an alteration in atomic arrangement. The disturbing effects of impurities frequently cause variations in physical properties which might be erroneously interpreted as a significant change by the former conception. Although allotropy may be more frequently considered to denote a crystal structure transformation, it seems advisable to use "polymorphism" so there will be no doubt as to the nature implied.

Fig. 4—Hexagonal close-packed structure, (a), (b) Close-packed hexagonal unit cell and packing of spheres in contact.⁶ (c) X-ray photograph of close-packed hexagonal zinc. Mo-K α radiation.

The much discussed phase change from α to γ iron at 1668°F. (909°C.), on heating, is the basis of steel heat treating. For a considerable period of time there were supposed to be four different structural forms, namely, α , β , γ and δ iron. However, X-ray analysis has established the nature of the transformations by the examination of pure electrolytic iron at elevated temperatures in a specially designed camera.⁸ It now appears that the so-called " β " iron is not a unique modification, that α and δ have the same structure and that pure iron therefore exists in only two different crystal forms corresponding to two polymorphic transformations, $\alpha \rightleftharpoons \gamma$ at A_1 , and $\gamma \rightleftharpoons \delta(\alpha)$ at A_4 . Pure α iron is body-centered cubic while the γ form has a face-centered cubic structure. X-ray analysis is a very reliable and convenient method for investigating polymorphic transformations at room or elevated temperatures.

Alloy Structures—When two metals are melted together and then solidified, a number of different structures may result. The various types are derived from the degree of mutual solubility of the component metals, their ability to combine or form intermediate phases, and the effect of temperature on these tendencies. The structural types which two elements may assume in the solid are graphically represented by constitutional diagrams, page 388, and are characterized by: (1) elements or metals; (2) solid solutions; (3) intermediate phases; and (4) superlattices.

A metal may occur in an alloy system where one metal is immiscible in the solid state in the other metal. The three symmetrical atomic arrangements typical of the common metals are illustrated in Fig. 2, 3 and 4. If the metal is not polymorphic, the same crystal structure will exist up to the melting point.

A solid solution of two or more metals is defined as a phase in which the crystal lattice of one component is retained. This would include continuous solid solutions and restricted solutions such as the end (terminal) phases of diagrams exhibiting immiscible regions (eutectic) and intermediate phases. Solid solutions, either complete or partial, may be divided into two types: The general or substitutional class, and the more limited interstitial group. When the solute atoms replace or are substituted for some of the atoms of the solvent lattice, the solution is termed substitutional. In the second, or interstitial type, the solute atoms are dispersed in the vacant spaces between the solvent atoms, that is introduced in the lattice in addition to the solvent atoms. The interstitial solutions occur infrequently and are confined to systems where the diameter of a solute atom is appreciably

Precision X-ray investigations of the elements have disclosed at least fifteen metals (beryllium, calcium, cerium, cobalt, iron, lanthanum, manganese, nickel, rhodium, thallium, tin, tungsten, uranium and zirconium) to exist in two or more different crystal forms. The names of the polymorphs, the type of space lattice, and the temperature range of stability have been tabulated.⁷ In addition to the metals, carbon, oxygen, nitrogen, phosphorus, selenium and sulphur have polymorphic modifications. The elements arsenic, antimony, bismuth, erbium, neodymium, praseodymium, ruthenium and possibly silver and strontium may be polymorphic.

The classic example of polymorphism is the transition of metallic white tin to the gray powder at 18°C., frequently called the tin pest. The white type is tetragonal and the gray tin variety, diamond cubic.

smaller than that of the solvent atom. Boron, carbon, and nitrogen are prone to form interstitial solutions with the transition elements, for example, carbon in γ iron (austenite).

Substitutional solutions may contract or expand the dimensions of the solvent metal cell depending on the size of the replacing solute atoms. An interstitial solution always enlarges the solvent lattice. The above discussion of the structures of metals would apply to solid solutions in as much as their crystal structures are generally simple and are similar to at least one of the component metals.

Intermediate phases are frequently referred to as "intermetallic compounds" or solid solutions, depending on certain phenomena and preference of definitions. It has been difficult in the past with the older methods of determining constitutional data to define the limits where a solid solution begins and a compound terminates. No satisfactory classification of intermediate phases was evolved until the advent of X-ray analysis. Now the term intermediate phase is used to denote those products of intermetallic reactions of two or more elements having a different space lattice from any of the components.* An intermediate phase may have a restricted or extended range of homogeneity. A variable composition is obtained by a change in the numerical atomic ratios of the elements composing the phase effected generally by atomic substitutions and infrequently by interstitial additions. In several instances two atoms, or a chain of atoms, replace a single atom in a substitutional region of an intermediate phase. The crystal structures of some intermediate phases are simple (Fig. 2-4), but many crystallize in complex arrangements which could not be adequately described in the allotted space.

A new structural arrangement called a superlattice has recently been discovered. There has been much discussion as to the classification of a superlattice structure such as a solid solution, intermediate phase, or "intermetallic compound." As this formation may occur in a homogeneous alloy with no appreciable alteration in the crystal structure, a superlattice may best be considered to be a modification of a solid solution or an intermediate phase, depending on the parent arrangement.

A substitutional solid solution exhibits, in most cases, a random or disordered distribution of the solute and solvent atoms in the solvent cells. However, some solid solutions when slowly cooled, or annealed at low temperatures, possess definite ordered positions of both atoms in the solvent space lattice (superlattice). This resorting of atoms may occur in a solid solution when two elements, A and B, exist in concentrations approximately represented by the formulas AB and A_2B such as CuAu, Cu₃Au, Cu₃Pd. Also intermediate phases of variable compositions in the range of the same atomic proportions as above may experience an order-disorder change, as the β phase CuZn. Superlattice formations may be accompanied by marked variations in physical properties such as specific heat and electrical resistivity.

It would appear that the ordered distribution is the stable condition at low temperatures in the susceptible compositions because the atoms meshed together with a lower degree of internal energy than in one of disorder. At high temperatures where the alloy is less rigid, thermal movements tend to shuffle the atoms into random positions. The transition is not so abrupt as transformations involving a phase change, but gradual so that many intermediate stages may be encountered. X-ray methods can accurately follow the process in either direction as the ordered atoms give diffraction effects in addition to the reflections characteristic of the parent lattice. The intensities of the extra superlattice lines progressively decrease as the ordering diminishes, becoming fainter, and finally the lines vanish when the disordered distribution is attained.

* This table was compiled by the Subcommittee on Physical Constants. The membership of the subcommittee was as follows: R. L. Kenyon, Chairman; J. B. Johnson, H. W. Russell, and C. S. Barrett.

The subcommittee solicits additional data and corrections for future revisions of this table. Communications should be directed to J. E. Donnellan, Sec. of the Committee, 7016 Euclid Ave., Cleveland.

between elements. In general, the data are as published in the various sources from which they were selected.

The articles in this Handbook which deal with the individual elements should be consulted for more complete information, especially regarding minor variations and effect of special treatments on the properties listed.

Properties of Metals at Low Temperatures

By R. K. Hopkins* and H. S. Blumberg†

General—Large sized pressure vessels are used mainly in the petroleum and chemical industries. In the former, most common application is in the oil dewaxing process where propane or some other suitable liquid is used as a refrigerant at temperatures in the range -40 to -75°F. and at high pressures. In the chemical industry a number of heavy walled pressure vessels are operating at temperatures as low as -150°F. Operating temperatures as low as that of liquid air have also been reported.

Because of the danger incident to the use of low vapor pressure liquids such as propane, the utmost care should be exercised in selecting materials for this service. Attention should be given to composition, melting history, mill processing, methods of fabrication, and heat treatment.

Definition of "Low Temperatures"—The definition of the term "low temperatures" is of necessity arbitrary. It is felt that the range of temperatures included should be as wide as possible, particularly since many metals are quite sensitive to slight lowering of temperature below room temperature, and in some cases even at temperatures somewhat above atmospheric. Accordingly, "low temperatures" as used in this article will refer to all temperatures below room temperature. Wherever the term is used specifically, a definite temperature range should be mentioned.

Importance and Relation of Welding—A great many large parts used at low temperatures are fabricated by welding. Welded joints are usually considered to consist of three zones which merge into each other, namely, base metal, weld metal proper, and the heat affected zone between the two. Therefore, the properties of a welded joint at low, as well as room, temperature should be considered with reference to these three zones.

Where welding is part of fabrication procedure, tests should be carried out to insure weld quality, particularly with reference to impact resistance. Test bars should be notched at various locations in the welded joint, through the weld proper, junction of weld and heat affected zone, the center of the heat affected zone, junction of heat affected zone and base metal, and the base metal proper.

It is important that, wherever possible, laboratory tests be augmented by tests on large models having the same symmetry as a full sized vessel. Such tests are extremely valuable, particularly when a new material is being used for the first time.

Forms Used for Low Temperature Service—Pressure vessels and other large parts are usually made from large rolled plates. Smaller parts are made from wrought material and in many cases castings are satisfactorily used.

In the majority of cases, operating temperatures do not fall below -150°F. Properly made low carbon steel is satisfactory down to -100°F. and certain low alloy steels give good impact values down to -150°F. Where operating temperatures are below -150°F. , special materials such as austenitic stainless steels and certain nonferrous metals should be used.

Wrought materials in rolled form are usually used for pressure vessels. The directional properties must be considered, as it is usual to find that transverse bars are lower than longitudinal ones in ductility and shock resistant properties as determined by laboratory tests. Segregation is also an important factor and thus, where large plates are fabricated, tests should be made from representative parts of the plate. Because of the extreme dimensions of large plates, it is practical to heat treat only by annealing or normalizing. Thus a number of compositions which would meet notched bar shock test requirements in the quenched and tempered condition are not used in heavy sections which do not lend themselves to drastic heat treatments.

Where castings can be used, such as in smaller parts, the fabricator has at his command many more compositions than are available for large heavy plates. In general it may be said that for castings there can be used all those materials satisfactory for heavy plates. However, the castings should generally be quenched and tempered, although in a number of compositions simple heat treatment will suffice.

*Director of Metallurgical Research and Development, and †Chief Metallurgist, M. W. Kellogg Co., Jersey City, N. J.

Properties of Metals at Low Temperatures—The lowering of the temperature of metals below room temperature is generally accompanied by an increase in the tensile strength and yield point and a lesser decrease in elongation and reduction of area as measured in a tension test bar. The property which is affected most by lowering temperature is the resistance to shock.

Tension Test Properties—There is a large amount of data available on tension test results on various compositions at low temperatures. Selected results are given in Tables I-III, covering carbon steels, alloy steels, cast irons, and nonferrous alloys.

Impact Properties—Interpretation of impact data on a quantitative basis with relation to use in design and in service is extremely difficult for a number of reasons. The phenomenon of the shock resistance of steels is extremely complex and does not lend itself to simple analysis. The fundamentals of impact testing are still far from being understood and, more important, therefore, is the fact that no quantitative use of impact tests is made in design. The range of such service factors as notch effect, velocity of blow, energy of blow, or combination with other stresses, are difficult to vary sufficiently in the laboratory to evaluate properly.

Rational use of data is based on experience, in that service history of metals of known impact properties dictates acceptable or unacceptable material. It is generally accepted that a Charpy ft-lb. value is satisfactory upon the basis of 10 ft-lb. minimum for subzero service.

When impact tests on ductile materials are carried out, an unnotched specimen

will usually bend as in a slow bend test with no failure. This takes place even at extremely low temperatures in most materials which fail with low absorbed energy values in notched sections. Accordingly, unnotched bars are of little value in determining differences between various materials. In design and manufacture notched and sudden changes in section should be avoided.

The Charpy and Izod impact tests are most commonly used. Details of these tests will be found in another article in this Handbook. The Izod test is extremely sensitive to changes in notch and results are somewhat more erratic than in the Charpy test when the keyhole notch is used in the latter. There is a constantly growing tendency, therefore, for specifications to contain requirements upon Charpy keyhole impact specimens. In the earlier literature, Fremont impact tests were reported, but this machine is only infrequently used today.

A recent impact test which appears unusually promising is the tensile impact test. It is expected that this test will come into more prominent use, because it is possible to obtain information as to the effect of velocity of the blow to a much greater degree than in the other impact tests.

It should be mentioned that all impact tests made today give "single blow" data. There appears to be no data on repeated impact tests at low temperatures.

Carbon Steels—Herty and co-workers¹ have made a thorough study of the effect of deoxidation on the impact strength of carbon steels at low temperatures. Compo-

sitions studied varied from 0.14-0.48% carbon. Correctly deoxidized steels with 0.22% carbon and less had satisfactory low temperature values down to -40°F. , while 0.48% carbon steel showed low results at -2°F. even though correctly treated. Herty points out the harmful effect of overheating in heat treatment and the decided lowering of the impact values if the steels are not properly normalized.

The low temperature Charpy impact properties of carbon steels are related to composition, melting history, heat treatment, and microstructure. Thus, when low carbon steels are made without being properly deoxidized, the authors¹¹ have shown that impact properties drop off suddenly in the vicinity of 0°F. , whereas when these steels are properly treated in the melting process, good values are obtained down to -100°F. All of these steels were found to be readily weldable, and the test values easily passing the Boiler Code requirements for pressure vessels. Table IV gives the average results of three impact tests of each of sixteen normalized and stress relieved carbon steels made with varying deoxidation practice. Impact values of weld metal are also given. It will be noted that the silicon and aluminum killed heats maintained acceptable impact values down to -100°F. , while one of the heats deoxidized with silicon alone gave poor or erratic values at 0°F.

*H. W. Russell.

As pointed out by Sands,⁴ carbon content of carbon steels is a factor. Aluminum killing is effective only when the carbon content does not exceed 0.30%. Above this percentage, carbon exerts a harmful effect even when steels are aluminum killed.

Kinzel and co-workers⁵ conclude that "aluminum killed, normalized, plain carbon steels of otherwise appropriate analysis, in small sections, are satisfactory for engineering service at temperatures down to -112°F. " They further state that, "welds produced with carbon steel electrodes having a combustible or mineral coating show sufficient energy absorption on low temperature notched bar impact testing to indicate their fitness for engineering service at temperatures down to -112°F. "

It is apparent, then, that properly deoxidized low carbon steel is satisfactory for service down to -100°F. These steels represent metals of lowest cost for low temperature service. They are easily weldable and weld properties are satisfactory.

Nickel Steels—The 2¼% nickel and 3½% nickel steels have shown excellent low temperature impact properties. Sands⁴ gives the following values for normalized steels of 0.20% carbon content:

Nickel, %	Brinell at room temp.	Charpy Impact Resistance, ft.-lb. Room Temp. -50°F.	
0	127	80	7
1	146	94	30
2	155	88	35
3	168	88	40
4	187	75	50

The effect of carbon in conjunction with nickel in normalized steels is pointed out in the following:

Nickel, %	Carbon, %	Charpy, ft.-lb.	
		Room Temp.	-50°F.
0	0.33	25	5
1	0.22	85	20
2	0.16	95	43
3	0.12	110	70
4	0.04	172	170

The authors⁴ describe the fabrication of a full sized 2¼% nickel steel pressure vessel, including two types of welding, heat treatment, and testing. Pressure vessels are ordinarily given a final heat treatment, as a unit, consisting of stress relieving at 1100-1200°F. followed by furnace cooling. Base metal and welded joints were shown to have acceptable properties at -75°F. and to easily pass Boiler Code requirements. Deposited weld metal of 2¼% nickel steel composition gave better values than ½% nickel welds at -50°F. Poor impact values resulting from too high a normalizing temperature were found. Microscopic studies pointed to the beneficial effect of small pearlite-ferrite grain size on base metal notched bar values.

Moses' reports on the excellent values obtained in the weld and base metal of 0.20% carbon, 3% nickel steels for pressure vessels. High values are shown at -100°F.

The results of a great deal of test data on low nickel steels are furnished in Properties of Nickel Alloy Steels at Low Temperatures.⁵ Important conclusions noted are: 1. Nickel steels of the pearlitic type containing 2-5% nickel remain quite tough at temperatures down to at least -100°F. 2. Nickel is equally as beneficial in pearlitic steel weld deposits as in rolled steel. 3. Normalizing pearlitic nickel steels at temperatures somewhat over the critical range gives values which are satisfactory for service down to -100°F. 4. Quenching and high tempering of low carbon, low and medium nickel steels have given good notched bar values at extremely low temperatures. 5. Improvements comparable to those effected in wrought steels are conferred by nickel upon cast steels as well. Cast steels should be heat treated by double normalizing and tempering.

An excellent comprehensive study of 2¼% nickel steels with special consideration for the fabrication of a dewaxing plant to operate at temperatures as low as -75°F. is reported by Aldridge and Shepherd.⁶ A large amount of data are available involving study of impact testing procedure, welding, effect of heat treatment upon plate as well as castings and piping. All of the conclusions point to excellent properties of various parts of properly heat treated material of this composition.

The low nickel steels when properly deoxidized are satisfactory for temperatures down to at least -100°F. These steels are only slightly more difficult to weld than the carbon steels because of greater air hardening tendencies. Many vessels of the 2¼% nickel composition are in service today at -50°F. This composition, however, is about twice as expensive as carbon steel.

Low Chromium Alloy Steels—Egan, Crafts and Kinzel¹⁰ have made extensive study of the low temperature properties of a great many combinations of low alloy steels with alloying elements of chromium, nickel, manganese, vanadium, molybdenum, zirconium, copper, and silicon. Their conclusions are as follows: 1. Many normalized low alloy steels are suitable for engineering applications down to -112°F. 2. Zirconium and vanadium markedly improve the low temperature impact strength of normalized low alloy steels. 3. When suitably combined with another alloy, chromium, nickel, copper, manganese and molybdenum improve the low temperature impact strength of normalized low alloy steels, the highest values being obtained with the chromium copper combination (0.12% C, 0.75% Cr, 0.50% Cu).

These writers¹ have made further study of the chromium copper combination, in which consideration was given to the effects of various deoxidizers, to mass effect and to properties of welds. It is concluded that:

Notched bar impact values obtained in steels at low temperatures fall into various energy levels. This phenomenon is a function of the nature of the material and is not due to minor variations in the preparation of the test specimens and test procedure.

Chromium-copper aluminum killed low alloy steels are satisfactory for engineering service at temperatures down to -148°F. and may be used in larger sections than plain carbon steel.

Welds produced . . . indicate their fitness for engineering service down to -112°F.

The present authors report that a number of vessels have been built of the chromium-copper aluminum killed steel. However, in practice it was found that commercial heats did not yield as high impact values as indicated by laboratory heats. Further, heavy plates had surfaces which were not wholly satisfactory.

Accordingly, about ¼ % nickel was added to the chromium-copper composition and surface defects were eliminated together with improvement in Charpy impact values. Table V shows the relation between normalizing temperatures from 1650-1900°F., followed by stress relieving, microstructure, and low temperature impact properties from +70° to -148°F. Weld data are also given. Best values at -148°F. are obtained when normalizing is carried out slightly above the upper critical point. The heat affected zone values are superior to base metal proper at lowest temperatures of impact testing. Weld test data of more recent origin than values given here prove that 10 ft.-lb. at -150°F. are met.

Low Alloy Steels—Herzig and Parke,¹¹ in attempting to determine what steels could meet an arbitrary minimum Charpy strength of 10 ft.-lb., when tested at low temperatures encountered in service, obtained data on the following S.A.E. compositions: 4130, 4140, 4615, 4640, 4815, 4340, 4015, 2330, 3135, 3240, 6145, and 1045. Specimens were tested after three heat treatments, normalizing at proper temperature, quenching and tempered to 200 and 300 Brinell. The beneficial effect of heat treatment was shown, also the superiority of alloy steels to the carbon steel. It was observed that the element molybdenum appeared more effective in improving impact strength at low temperatures when used in conjunction with nickel or chromium or both, especially in the normalized condition. It was concluded that only steels 4615 and 4815 were satisfactory (in excess of 10 ft.-lb. Charpy at -94°F.) as normalized, while in the 200 Brinell condition all steels except 1045 had satisfactory low temperature impact strength. In the quenched and tempered to 300 Brinell condition, all steels except 4015, 3135, and 1045 had satisfactory subzero impact properties. The normalized and 300 Brinell steels were tested at -94°F. minimum, while the quenched and tempered specimens were tested as low as -310°F.

A nickel-molybdenum-vanadium steel¹² used in cast valves is reported to be excellent for shock resistance at subzero temperatures. Heat treatment is drastic and consists of "an homogenizing treatment followed by an oil quench and high temper." Properties given are: Room temperature, tensile strength 107,000 psi.; yield point 88,000 psi.; elongation 22% in 2 in.; reduction of area 61%; and Charpy impact at -150°F. 20 ft.-lb.

High Chromium-Nickel Steels—The high chromium-nickel austenitic steels retain notched bar toughness down to extremely low temperatures. Colbeck, MacGillivray, and Manning¹³ report the following.

C	Composition, %		Room Temp.	Izod Impact Resistance in ft. lb. at			Soaked in liquid air ^a
	Ni	Cr		-85°F.	-184°F.	-292°F.	
0.11	10.0	14.7	116	99	86	80	79

0.45 ^b	10.2	13.8	61	14	...
0.06 ^c	10.5	13.45	117	118	...	118	117

^aTested at -292°F. after soaking in liquid air for from 7 to 14 days.

^bThis steel contains 3.65% manganese.

^cThis steel contains 4.07% manganese

Russell and Welcker¹⁴ obtained the following results on a chromium-nickel steel:

Charpy Impact Resistance, ft.-lb. at °F.

C	Ni	Cr	Condition	Room Temp.	+32	-4	-40	-76	-112
0.09	9.24	17.54	Annealed	80	78	77	78	81	82
			Cold Worked	35	33	31	30	29	29

High Nickel Steels—Chevenard's tests made on a Fremont machine using test bars 35 x 10 x 8 mm. with a notch 1 mm. deep are presented graphically in Fig. 1. It is apparent that when nickel is present in excess of about 45% there is no decrease in resistance to impact at temperatures at least down to that of boiling

liquid air (-310°F). Such steels are, therefore, suitable for parts of liquid air machines and other applications involving service at subatmospheric temperatures. A steel developed by Chevenard especially for this purpose contains 55-60% nickel, 1-3% manganese and 0.2-0.4% carbon. It is reported to have the following properties at liquid air temperatures: Tensile strength, 114,000 psi.; elastic limit, 57,000 psi.; elongation, 40%; reduction in area, 55%; and Fremont impact, greater than 45 kg-m. per sq. cm.

Fig. 1—Effect of nickel upon the Fremont impact resistance of iron-nickel alloys at the temperature of boiling liquid air.

Fig. 2—Charpy impact tests on stainless irons.

1. 18% Cr, 8% Ni, Quenched in Water from 1950°F . 2. Same as 1, Cold Drawn. 3. 18% Cr, Annealed. 4. Same as 3, Cold Drawn. 5. 14% Cr, Annealed. 6. Same as 5, Cold Drawn.

High Chromium Steels—The high chromium compositions should not be used for low temperature service where shock is a factor of any magnitude. Sergeson compares annealed and cold drawn stainless compositions of 18-8, 18% and 14% chromium and shows the low values obtained on the plain chromium compositions (Fig. 2).

Russell and Welcker also bring out the low shock resistance of this group:

Composition, %			Condition	Charpy Impact Resistance in ft.-lb. at—				
C	Ni	Cr		Room Temp.	32°F .	-4°F .	-40°F .	-76°F .— 112°F .
0.07	...	13.85	Annealed	39	38	4	25	1
			Heat Treated*	28	3, 25, 6	..

* 1850°F . oil; 1025°F . air cooled; 1035°F . water.

Cast Irons and Wrought Irons—Neither of these materials are recommended for low temperature service where shock is liable to be present. Russell² summarizes information on cast iron. Scattered and limited data will be found in the literature on wrought iron.

Nonferrous Materials—Copper, which shows excellent values at room temperature, is little changed in notched bar impact properties at extremely low temperatures. Pure nickel and high nickel-copper alloys also retain good impact properties at low temperatures. Aluminum and brass are likewise little affected as temperature is lowered.

Brinell Hardness—In general the Brinell hardness of metals increases with decrease in temperature, paralleling to some degree the tensile strength. However, a number of nonferrous compositions are distinct exceptions.

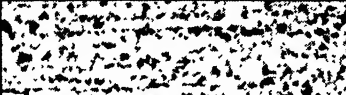

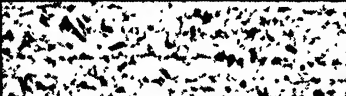

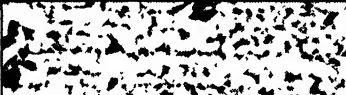

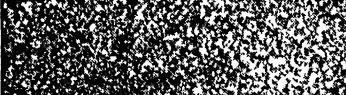

Fatigue—Little work has been done on the fatigue properties of metals at low temperatures. Indication is that endurance limit rises as temperature is lowered.

Testing of Metals at Low Temperatures—General—By far the majority of tests carried out today are made upon impact bars. Many new specifications, particularly those involving welded structures, are requiring that impact tests be met. These

tests are also being used as a check of the suitability of metals and welded structures to operate at low temperatures. Tensile tests are only infrequently made.

Measurement of Temperature—Temperatures down to -328°F . may be measured with calibrated pentane thermometers. Toluol thermometers are also satisfactory for measurement as low as -148°F . Thermometers should be checked frequently over a period of time. They offer the simplest means of temperature determination.

Table V
Microstructure and Charpy Impact Values at Low Temperatures*

*Condition	Etched in 4% Nital-100x	Charpy Impact, Ft.-Lb.

Some prefer to use copper constantan or iron constantan thermocouples. This means is the most accurate. Practically all laboratories use thermometers for routine work.

Methods of Cooling for Low Temperature Testing—For attaining desired low temperatures there are three general methods of cooling which may be used: 1. Controlling the temperature of an entire room. 2. Circulating a cold medium around the specimen before and during the cooling while test is being made. 3. Immersing specimens in a cold medium of controllable temperature, then transferring quickly to testing machine.

The method of cooling depends upon the type of test to be carried out and the temperature it is desired to attain. Obviously the first scheme mentioned will probably give the most accurate results. However, it is the most complex and in most cases is not necessary. Choice of cooling method is also related to length of time required in testing. Where a test can be carried out in a few seconds, such as in a single blow impact test, the third method, which is the simplest, should be used. Only in impact testing may this method be used, as in other tests length of time involved is sufficient to cause considerable temperature rise in a short space of time. It has been shown that where tests are made in seven seconds or less, no appreciable rise in temperature occurs. In tests where plastic deformation occurs temperature rise results and should be considered in interpreting results.

For impact testing the authors use (a) Acetone and dry ice, to $-100^{\circ}\text{F}.$; and (b) Propane and liquid nitrogen, for lower temperatures.

Mechanical Working—No specific studies have been made, but it has been general experience that wrought materials are superior to castings, after best heat treatments are carried out.

Heat Treatment—Proper treatments improve impact values of practically all steels. The more drastic the heat treatment the lower the temperature at which notched bar values fall off, therefore, quenching and high tempering the pearlitic steels gives superior impact values to normalizing.

The present writers were able to obtain more than 75 ft.-lb. at $-75^{\circ}\text{F}.$ on a Charpy keyhole specimen of rimmed steel when it was water quenched in $\frac{1}{2}$ in. sq. section, but when treated as a $1\frac{1}{2}$ in. plate values were extremely low at this temperature.

Microstructure—There appears to be a relation between impact values on notched bars and actual grain size. Sergeson shows that impact specimens of wrought iron broken at $-4^{\circ}\text{F}.$ broke along the grain boundaries with practically no distortion of adjacent grains, whereas at room temperature and higher considerable distortion was apparent in the microstructure.

Melting History—Effect of melting practice in low carbon steels is given by Epstein in Fig 3:

Proper deoxidation has been shown to be of great importance in making carbon and low alloy steels. Aluminum killing in particular is beneficial. Killing with silicon alone has not been found to be as effective as when aluminum or other deoxidizer is also used.

Kinzel and co-workers point to the effectiveness of aluminum, zirconium, vanadium and columbium.

Mass—Since the relation exists between impact values and grain size, it is to be expected that mass is a factor. Many compositions which are suitable in small cross section are not acceptable in larger masses. The effect of mass, may, of course, be overcome in degree by heat treatment.

Fig. 3—Low temperature impact properties of carbon structural steels made by various processes.

Fluidity of Metals

By Charles W. Briggs*

The term "fluidity" refers to the property of a metal which allows it to flow freely and evenly into a mold and fill it before such freezing occurs that would offer an obstruction to its further flow. It is a property sometimes referred to as "castability," "runnability," "flowing power," or "fluid life." "Fluidity," which is the word often preferred, has the disadvantage that in the past it had a specific physical meaning; namely, the reciprocal of the coefficient of viscosity. However, in recent literature the term "coefficient of liquidity" is preferred for this constant, thus allowing the broader field to be covered by "fluidity." There are many, however, who have not accepted the term in its new sense as it is believed that old associations stand in the way of its adoption, and hence the terms given above are often preferred.

When using "fluidity" in its broader aspects, it must be remembered that it should by no means be identified with viscosity. The viscosity of a fluid in the physical sense is concerned with movements in the interior of the liquid, and thus at a given temperature it is a definite physical constant. The viscosity test, which is rather simple and accurate at relatively low temperatures, is exceedingly difficult to perform at the higher temperatures required by molten iron and steel. Foundrymen have, therefore, found it necessary to devise a more simple method for the study of fluidity. In general, this test consists of pouring molten metal into sand molds which contain a cavity in the form of a spiral. This test is concerned primarily with the fluid life of the metal and measurements refer both to the metal and to the mold.

The fluidity or fluid life of metal is dependent on two major factors; (1) properties of the metal, and (2) variables of testing. The factors relating to the metal are those of viscosity, surface tension, surface films, gas content, suspended inclusions, and the mode of solidification and crystallization. The second set includes the form of the test piece, the casting head, the properties of the mold, the rate of pouring, and the degree of superheat.

Properties of the Metal—Viscosity—There is quite a general belief that molten metals differ widely in viscosity, and that metals that flow poorly have high viscosity. In reality, the viscosity of metals is very low, the kinematic viscosity being less than that of water in all cases investigated.¹ Also, since viscosity changes only slightly with change of temperature, it is really a negligible factor in casting. It is unnecessary to go into the details of the methods employed in measuring viscosity. It may be pointed out, however, that there are two main methods of study. In one case liquid metal is allowed to flow under a constant head through a capillary tube and in the other some form of torsional pendulum is used. The first can be applied only to metals of low melting point since the capillary tube is constructed from glass or quartz. The second method may be used at relatively high temperatures with a fair degree of success since the apparatus consists essentially of refractory cylinders or discs suspended in the molten metal operating in torsional oscillations. Studies on tin and lead,² various brasses, bronzes, and copper,³ and cast iron⁴ have been undertaken by the torsional pendulum method.

A critical review of the published data on viscosity was prepared by Andrade.⁵ In this he develops a new theory of the inner mechanism of the viscosity of liquids which has enabled him to calculate η with close approximation of the experimental values for a number of metals. These may be listed as follows:

Substance	At atmospheric temperature	η -Poise
Water	Just above the melting point	0.0105
Mercury		0.021
Lead		0.028
Tin		0.020
Copper		0.038
Iron		0.040

*Technical Adviser, Steel Founders' Society, Cleveland.

It may be concluded, therefore, that the viscosity of metals is only a small multiple of that of water; and that the kinematical viscosity (or viscosity divided by density), on the basis of which the effects of stresses due to viscosity in modifying the existing motion of a fluid may be compared, is considerably lower than that of water. It is therefore evident that the viscosity of metals plays only a minor part in their casting behavior, and that the effects which have been attributed to viscosity are mainly due to other causes.

Surface Tension—When molten metals are poured into a sand mold, the mold surface is not wetted.¹¹ The rise of steel in a narrow channel is impeded by the surface tension of the liquid metal. This effect becomes less marked as the diameter of the passage is increased.

Values have been tabulated by Bircumshaw⁶ of the surface tensions of some of the common metals, at temperatures not much above their melting points.

Surface Tension of Some Common Metals

Metal	Temperature °C.	Surface tension (dynes per cm.)
Antimony	640	350
Bismuth	269	378
Lead	327	452
Mercury	20	465
Tin	232	526
Cadmium	320	630
Zinc	419	758
Silver	998	923
Copper	1131	1103
Gold	1120	1128
Iron (2.2% C)	1420	1500
Iron (3.9% C)	1300	1150

The deductions that may be drawn from this table are that: (1) the surface tension of metals increases as the melting point increases; (2) from the figures for the two alloys of iron and carbon, steel has a higher surface tension than cast iron; and (3) since the surface tension of water at 20°C. is only 81, the values for metals are relatively high.

It has also been determined that, in general, surface tension diminishes, as a rule, with increasing temperature.

A high value of surface tension has the effect of increasing the pressure required to cause the metal to enter and flow along a narrow channel, but the direct effect of the true surface tension of many metals is almost overshadowed by the effect of surface films whose influence is equivalent to that of greatly increased surface tension.

Surface Oxide Films—It has been found that surface films affect the flowing power, especially of nonferrous alloys. In a study on brass ingots, Genders and Bailey¹⁰ showed that the oxidation of a stream of molten brass by contact with air gives rise to a surface film of zinc oxide which raises the apparent surface tension of the metal, restricts the flow, and is an inevitable cause of ingot defects.

Determinations of the apparent surface tension of oxidized and clean, molten aluminum have been described by Portevin and Bastien.¹¹ They show that the effect of the oxide film is to increase the value nearly three times.

This surface film property of aluminum also affects alloys in which it is present. According to Desch³ the difficulty of casting aluminum bronze is caused by the formation of such a tough skin that it hinders pouring and, by becoming broken into fragments, is entangled in the metal, making a dirty casting.

When the oxide is soluble in the molten metal, no film is formed, so that copper, cast iron, and nickel pour in a clean stream.

According to Greaves¹² there is some evidence which strongly suggests the existence of films in an over oxidized steel killed with aluminum. Such a surface film would reduce the fluidity. A chromium-rich oxide skin on steels is thought to have a marked effect on their fluidity.

Gas Content—One difficulty in applying data relating to the effect of surface tension in the case of a metal flowing in a channel, arises from the fact that the

metal is often not in actual contact with the mold, but is separated from it by a thin layer of gas, either issuing from the metal or arising from the material of the mold. Gases that are given off from metal during its flow through a casting probably increase the resistance to flow. It is also probable, however, that gas issuing from the metal tends to prevent the formation or break up oxide films so that the fluidity is improved.

Suspended Inclusions—Solid matter in suspension causes a rapid rise in the apparent viscosity of a liquid as suspended particles do hinder flow. A liquid in which more than a small portion of particles is suspended will give a higher value than the same liquid free from solid particles.

Fluidity has been attributed by many steel foundrymen to the effect of dissolved oxides. There is no evidence to suggest that oxide in solution would in itself improve the fluidity of cast steel. It may, however, alter the surface tension or produce some effect on surface oxide films.

Solidification and Form of Crystallization—Test on binary alloys led Portevin and Bastien¹⁰ to formulate two laws: (1) Fluidity varies inversely to the interval of solidification. It will be greatest when the melt is homogeneous (as in the case of pure metals, or eutectics), and is least for the saturated solid solutions. (2) Fluidity depends on the crystal form of solidification and is relatively much greater when the liquid forms crystals with convex faces than when it forms dendrites.

The above principles have been confirmed by other workers.

Variables of Testing—*Form of the Test Piece*—Various types of test bars have been used to measure fluidity in the past. However, for a given metal at a given temperature, spiral test bars will be longer and the test more sensitive, as the metal cools more slowly. Therefore, a geometrical form should be adopted of such a section that for a given volume of metal, the minimum surface for contact between the metal and the mold would be presented. For this reason the more recent investigators have used a spiral mold cross section of which approached semicircular shapes.

There are two designs based on the method employed for metal entry; the European design, Fig. 1, wherein a straight down gate is used and the American design, Fig. 2, that employs a horn gate.

Important data, especially on low melting temperature alloys, has been recorded, wherein permanent molds have been used. However, in the last few years sand molds have been used almost entirely since from the point of view of sensitivity, a mold should have the least possible tendency to chill.

Casting Head—One of the essential parts of the mold is the casting head and the metal reservoir. The height of these above the spiral affects the length of the spirals run. A reservoir must be provided to break the fall of the metal from the ladle and to supply an even flow of metal to the mold down gate.

Properties of the Mold—Variations in the temperature of the mold and the state of dryness of the mold affect the length of the spiral obtained. The permeability of the sand should be sufficient to assure an easy escape for the gas produced by the contact of the liquid metal with the mold. In order that an easy escape of gas or air from the mold be assured the end of the spiral should be well vented. The bond strength of the sand should be sufficient to avoid erosion of the sand by the liquid metal. Mold surfaces may cause variations in the length of spiral obtained. Factors that influence the character of the results have been noted to be: (1) grain size of the sand, (2) degree of moisture, (3) mold washes, and (4) surface coatings.

Rate of Pouring—The length of the test bar depends also on the speed of running the metal in the spiral. This speed of course depends on the rate at which the mold is poured. If the pouring rate varies between one test and another, the length will vary in the same way. Exceptional care must therefore be maintained to pour all molds at the same rate (preferably a fast rate) and that the pouring height above the mold will always be the same.

Fig. 1—European type of fluidity mold (Cury).

Fig. 2—The American, or Bureau of Standards type of fluidity mold (Saeger and Krynetsky).

Degree of Superheat—As the temperature of the molten metal is raised the length of the resulting cast spiral is increased. An increased length of spiral with increase of casting temperature does not necessarily imply that the metal is more fluid at the higher temperatures, since the additional spiral length may be due entirely to the increased ranges of temperature, through which the metal cools while it is flowing in the spiral. It should also be emphasized, however, that the degree of superheat may alter the composition of the metal or increase surface oxide films or gas content to such a degree that the spiral length is affected.

Accuracy of Test Methods

Before proceeding to the results that have been obtained by testing methods it is necessary to emphasize that it is difficult to establish a correlation between these tests and actual foundry experience. In fact, little correlation has been established to date. Just why a better correlation has not been established is probably due to the inadequacy of the test methods in that so many factors are involved that only with extreme care is it possible to avoid erratic and meaningless results.

Fluidity of Low Melting Temperature Metals—Most of the experimental work on the fluidity of low melting temperature metals has been carried on by Portevin and Bastien¹³ in a permanent mold. The data, as set forth in Fig. 3, is very complete and is so plotted that fluidity values can be correctly evaluated. In Fig. 4 the curves for zinc and aluminum are plotted directly against the temperature and offer conditions of comparison with those as set forth in Fig. 3.

Fig. 3—Fluidity of low melting temperature alloys, permanent mold—spiral cross section area 0.170 sq. in. (Portevin and Bastien).

Fig. 4—Fluidity of zinc and aluminum permanent mold (Portevin).

Fig. 5—Fluidity of commercial aluminum sand mold—spiral cross section 0.066 sq. in. (Saeger and Krynetsky).

Fig. 6—The effect of alloying elements on the fluidity of aluminum, permanent mold (Portevin).

The only valuable studies that have been carried on in sand molds, using low melting temperature metals, have been those on aluminum. The results of Saeger and Krynetsky,¹⁴ Fig. 5, are quite typical of what may be expected with commercial aluminum. The authors studied the effect of various maximum heats on the fluidity. They explain the decrease in fluidity, with increase in heating temperature as caused by absorbed gas.

The effect that alloy additions have on the fluidity of aluminum is shown in Fig. 6. It may be noted from this figure that the

addition of some metals brings about a drop in the fluidity such as recorded by nickel. Others may act like magnesium to increase fluidity, and others such as silicon may play a dual role such as to decrease and then increase the fluidity.

The Fluidity of Brass and Bronze—Using the Bureau of Standards mold that they devised, Saeger and Krynetsky¹⁴ studied the fluidity of brass, Fig. 7. They obtained a straight line relation whereas Pilling and Kihlgren,¹⁵ using a modification of the Bureau of Standards mold with a spiral cross section of 0.098 sq. in. as

compared to 0.066 sq.in. of the former, obtained a slight curve for a comparable alloy, Fig. 8.

The Fluidity of Cast Iron—Studies on the fluidity of cast iron have been carried on by various investigators¹ using the permanent mold and sand molds of the European and American type. The most complete set of data, however, have been prepared by Perin and Berger.¹⁰ In Fig. 9, the relation between temperature, fluidity, and carbon content is portrayed. It may be seen from this diagram that if the casting temperature is kept constant, the fluidity increases with the carbon content up to the eutectic concentration (4.3% carbon), then decreases at higher carbon contents. Also, in the hypoeutectic region, there is a sudden increase in fluidity around 4.0% carbon.

Of course there are several constituents in cast iron other than iron and carbon. The influence of these elements on the fluidity of cast iron has also been investigated by Berger. Due to the fact that the additions of phosphorus and silicon influence the temperature of the liquidus, the fluidity comparisons are rather complicated, and for exact information the reader should turn to Berger's original work. However, for those interested in the study of irons, a general law may be formulated as follows: The eutectic mixtures are those which possess the greatest

Fig. 7—Fluidity of brass—virgin metal, copper 85%, zinc 5%, tin 5%, lead 5%—spiral cross section 0.066 sq. in. (Saeger and Krynsky).

Fig. 8—Fluidity of bronzes—green sand mold—spiral cross section 0.098 sq. in. (Pilling and Kihlgren).

Fig. 9—Diagram showing the relation between temperature °C, fluidity, and carbon content—sand mold—spiral cross section 0.078 sq. in. (R. Berger).

Fig. 10—Fluidity of cast iron—sand mold—spiral cross section 0.066 sq. in. (Saeger and Ash).

	T.C	G.C	CC	Si	S	Mn	P	Liquidus °C.
Iron A	3.56	2.85	0.71	2.62	0.016	0.21	0.85	1170
" B	2.91	2.05	0.91	2.07	0.023	0.17	0.68	1240
" C	3.71	2.81	0.90	1.16	0.054	0.58	0.10	1200

fluidity and, therefore, are those which are most likely to give perfect castings. If the hypoeutectics are considered, the only ones used practically, it is possible to say that the element regulating fluidity is carbon, next is phosphorus, and in a certain measure (under 1.00%) silicon. As to manganese, its influence on fluidity is of little importance. The amount and direction of its influence are essentially a function of the composition of the metal considered. Since, however, the modern commercial trend is toward the low carbon metals the fluidity of cast iron would depend more upon the increment in temperature above the liquidus than on the other recognized controllable factors.

Three commercial cast irons have been investigated by Seager and Ash¹⁷ and these are shown in Fig. 10. These authors state that the running qualities of these irons were dependent upon the liquidus temperature and apparently were not influenced by any previous maximum heating temperature prior to pouring of the fluidity test at a lower temperature. For a chosen pouring temperature, the heats of iron having the lower liquidus temperature have superior running qualities.

Fig. 11—Fluidity of an iron-carbon alloy—0.71% carbon taking the solidus as zero fluidity—sand mold—spiral cross section 0.091 sq.in. (Andrew, Percival, and Bottomley).

Fig. 12—Fluidity of iron-carbon alloys at 1600°C. (2912°F.)—sand mold—spiral cross section 0.091 sq.in. Andrew, Percival, and Bottomley).

He found that in the case of cast iron poured into a steel spiral mold that he could increase the length of the spiral from 51 centimeters to 81 centimeters by varying the mold coatings. The order of progressive increase was (a) linseed oil, (b) iron oxide, (c) graphite, (d) black lead, and (e) a thin layer of soot from an acetylene flame.

The Fluidity of Steel—There is little valuable information on the fluidity of steel, and that which is available is based on so few points that the curves so constructed may not be justified. In a study of iron carbon alloys, Andrew, Percival, and Bottomley¹⁸ predict the fluidity of several carbon steels. In Fig. 11 is presented a fluidity temperature curve of 0.71% carbon alloy, wherein the liquidus is taken as zero fluidity. Also, Fig. 12 shows the fluidity curve of iron carbon alloys at 1600°C.

Powder Metallurgy

By Charles Hardy* and Clarence W. Balke**

Definition—Powder metallurgy is the art of making objects by the heat treatment of compressed metallic powders with or without the addition of a nonmetallic substance. It may be applied to a single metal powder or to complex mixtures and the pressing operation may be carried out at ordinary or elevated temperatures. In many cases the results obtained by the use of this method are identical with those obtained by the orthodox methods of melting and casting. In many other instances, however, properties are developed which heretofore were unattainable.

Advantages of Powder Metallurgy—1. This method alone has made possible the production of refractory metals in useful forms. The extremely high melting points of such metals as tungsten, molybdenum, and tantalum forced the development of this process for their preparation in the form of workable ingots. Even if it could be produced commercially, the brittle, coarse grained tungsten made by fusion would be of little value. The nature of the method makes it possible to produce special forms of these metals, such as the nonsag variety of tungsten used in lamp filaments. This is accomplished by the use of certain materials added prior to the sintering operation. In short, the entire development in the field of refractory metals and their carbides in the form of cemented material has made the practice of this art a necessity.

2. The finished product contains the metals in the exact proportions desired. For this reason the composition of alloys can be consistently reproduced. For example 90-10 bronze, and 80-10-10 bronze, can be made of metal powders having a uniformity of composition unapproachable by foundry methods.

3. This process reduces or eliminates impurities introduced by conventional methods. The high purity obtainable in metal powders is retained. Iron may be produced from powder having a great purity and contaminated with manganese, phosphorus, silica or sulphur very slightly, if at all.

4. Aggregates or mixtures can be made of metals which are immiscible in the liquid state or which have widely divergent melting points. Important examples are lead and copper, copper and chromium, copper and tungsten, or copper and molybdenum. The last two compositions are used in the form of welding electrodes or switch contacts handling heavy currents. Good thermal and electrical conductivity is supplied by the copper constituent, and resistance to wear and high temperature is furnished by the tungsten.

In many examples of this type at least one of the constituents of the mixture may be fused during the heat treating operation. Localized alloying on the surface of the unfused grains may take place. Examples of this type are the hard cemented carbides and alloy magnet materials.

5. The method makes it possible to produce metals in which a nonmetal is uniformly disseminated. Current collecting brushes for dynamos and motors are made in this way from mixtures of copper and graphite. Under this heading bearings and bushings must be mentioned specifically since their production accounts for the consumption of large quantities of metal powders. The bearings which are used on a large scale are mixtures of copper, tin and graphite.

6. The dimensions of finished articles may be held within close limits. The pressing dies may be made with a high degree of accuracy, and after heat treatment the precision of the pieces may be increased by striking or coining. Articles so made compete with die castings. It has been found that the precision of the dimensions desired can be controlled to narrow limits, and with the use of coining presses, an accuracy of .001 in. is readily obtained for quite a number of metals or alloys. Even narrower limits have been secured by repressing and coining. Those practiced in the art have found that the type of die, type of powder, length of time of heat treatment and temperature of sintering can be so controlled that contraction or distortion can be held within narrow limits.

7. Economies in production can be effected in many cases. Materials are not lost during the manufacturing operations. When the conventional methods of melting, casting and forging are employed, losses occur due to slag and oxide formation and material may be removed by cropping, removal of flash, or by trimming. These losses may frequently reduce the weight of the finished product to $\frac{1}{4}$ that of the

*President, Hardy Metallurgical Co., New York City. **Research Director, Fansteel Metallurgical Corp., North Chicago, Ill.

material used. With such losses eliminated the more expensive metal powders may be employed to produce finished products on a competitive basis.

8. Special structural effects can be obtained which are not possible in the melting and casting process. Useful bimetal can be made. A layer of iron powder and one of nickel may be converted into a composite ingot by pressure. This can be heated and rolled to produce thin plate or sheet in which the two layers are perfectly welded together. The composite electrode of tungsten and copper may be considered an example under this heading. However, the most notable example of this type of work is the porous bearing. The method makes it possible to produce these bearings having a high degree of porosity of an interlocking character, permitting them to retain appreciable amounts of oil.

9. Lower temperatures than those previously required are often sufficient for the fabrication of certain materials; for example, platinum, iron-nickel-cobalt alloys and the refractory metals.

10. The method makes it possible to work with accurately controlled atmospheres. A neutral, inert or reducing atmosphere may be employed, or heat treatment may be carried out in a vacuum. Tantalum and columbium are heat treated in vacuum.

Limitations and Disadvantages of Powder Metallurgy—Obviously, powder metallurgy does not furnish the solution to every metallurgical problem. It has certain limitations, and even where applicable, difficulties may be encountered.

1. Except in the few cases where masses of metal powder can be heat treated without previous compression, the high pressure required to form the pieces establishes a definite limitation to the application of the process. This limitation is physical in character and resides in the special molds and heavy presses required to compress the powders. As the power of hydraulic presses is increased, larger and larger pieces may be handled, but in such cases the cost of the equipment may become excessive.

2. Many powders have a distinct tendency to cling to the walls of the die as the pressure is built up. This results in an uneven pressure throughout the mass and tends to limit the depth of the die which may be employed.

3. In some instances difficulty is encountered controlling the particle size of the powder. This should be considered merely a disadvantage and not a fatal limitation of the method.

4. Because of the great surface of metals in a finely divided state, difficulties arise due to the action of air and moisture. Occasionally these may be sufficiently great to warrant the provision of air conditioned rooms in which to carry out the operations.

5. In producing a new product considerable experimental work is still required, due to lack of knowledge concerning the welding and adhesion characteristics of the various metals with each other.

Metals Produced in Powder Form—Many metals are now obtainable in powder form but not all of them are of value in the practice of this art. The metals in general use are listed below:

Metal	Purity	Apparent Density
Aluminum	99% plus	0.75-1
Antimony	99% "	2.-2.50
Bismuth	99.90% plus	
Brass	70% Cu-30% Zn	
	65% Cu-35% Zn	
	90% Cu-10% Sn	
Bronze	99.90%	2.8-3.5
Cadmium	99.50% plus	2.5-3.5
Chromium	98.00% min.	
Chromium	98.00% plus	
Cobalt	99.8% "	
Columbium	99.60% "	2.-4.
Copper		
Gold		
Iron	99.50% "	
Iron (hydrogen reduction)	99.90% "	
Lead	99.90% "	4.6
Manganese	98.00% "	3.-6.5
Molybdenum	99.90% "	4.-5.
Nickel	99.65% "	2.5-3.5
Palladium	Pure	
Silicon	97.00% "	.50-.70
Silver		
Tantalum	99.8% "	5.3-6.0
Tellurium	99.00% "	

(Continued)

Metal	Purity	Apparent Density
Tin	plus 99.80%	1.5-2.75
Titanium	92.98% "	
Tungsten (hydrogen reduction)	99.00% " W	9.-10.
Tungsten (carbonyl reduction)	98.00% " W	
Vanadium	88.95% "	
Zinc	99.00% "	2.5-2.75

Practically all metal phosphides can now be made in powder form
COATED POWDERS—Silver coated nickel, molybdenum, copper, and copper coated silver and lead.

The above metals are available in various mesh sizes. The user, however, usually specifies 100, 200, or 300 mesh. Special requests calling for 25%, 50% or even all through 325 mesh can be met. For special purposes material much finer than that indicated here can be obtained by air separation, elutriation, or by other methods. Powders have been actually produced showing a maximum grain size less than 1 mill.

Production of Powders—Metal powders can be produced by various methods such as grinding, stamping, precipitation, atomizing, spraying, electrolysis, condensation, or reduction. The selection of the method to be used for a given metal will be determined, among other considerations, by its chemical characteristics and the nature of its compounds. Metal oxides can be reduced in hydrogen or with controlled atmospheres. The rate of heating and the rapidity of gas flow may be regulated to produce powders of varying particle size. Common examples of metals so made are copper, nickel, cobalt, molybdenum, and tungsten. On the other hand the oxides of tantalum and columbium are not reduced by hydrogen. Powders of these metals are made by the electrolysis of fused salts. In other cases, electrolysis of aqueous solution may be used. Some metals such as gold, silver and the members of the platinum group may be precipitated from the solutions of their salts by the addition of suitable reducing agents. Considerable quantities of iron and nickel powders are made by the decomposition of their carbonyls. In some cases calcium hydride is employed as the source of nascent hydrogen used in the reduction of such refractory oxides as, for example, chromium oxide, titanium, and zirconium oxides.

Characteristics of Metal Powders—The results obtained in the practice of this art will depend, among other things, upon the purity and physical characteristics of the powders used. In many instances it is necessary to maintain the amount of objectionable impurities below definite limits, while in other cases, beneficial impurities are added to the powder mixtures. Metals, in a finely divided condition, carry appreciable quantities of gas either dissolved or as surface films, and this fact must not be overlooked. In some instances the presence or absence of a given impurity of the order of a few hundredths of 1% determines whether the powder is usable or not.

The physical characteristics of the powders are also of great importance. These characteristics concern mainly the shape or structure of the particle itself and the particle size and the range of particle size. The shape of the particles is determined mainly by the method employed in their manufacture. Aluminum powder made by granulation is quite different from that made by stamping. Copper powder made by reduction is distinctly different from that made by electrolysis. The shape of the particles of metal powders produced by condensation, as in the case of zinc, or by the decomposition of their carbonyls, as in the case of iron or nickel, is distinctly spherical.

Since the physical characteristics of the powders often determine their fitness for use, they are subjected to careful tests and examination. Where the powders are sufficiently coarse the particle size and the particle size distribution may be determined by the use of metal sieves. However, this method is not applicable for particles finer than 400 mesh. (The diameter of a particle passing a 300 mesh sieve is about 53 microns.) In the case of finer powders, microscopic examination may be employed, or a measurement of the light blocking action of the powder in suspension in a liquid may be measured. This is especially true in the case of finished powders employed in the hard carbide industry where the particle size may range from 1-5 microns, or finer. The following table gives the relation between the micron, millimeter, and inch:

1.0 micron = .001 mm.	0.001 inch = 0.0254 mm.
1.0 inch = 25.4 mm.	0.0001 inch = 0.00254 mm.
0.1 inch = 2.54 mm.	0.00005 inch = 0.00127 mm.
0.01 inch = 0.254 mm.	0.00004 inch = 1. micron

It is frequently desirable to determine the apparent density of the powder, otherwise known as "loading weight." A common method used for this purpose is to determine the volume of a given weight of powder gently tapped down in a graduated cylinder, or it may be determined by a Scott volume meter. If the latter method is used the powder is allowed to drop through baffle plates into a cup or box of known volume. The powder is carefully scraped off level with the top of the box and weighed. A number of factors other than particle size itself may influence the value of the results obtained in this case. Variations in this loading weight affect the compression ratio when the powder is pressed. The physical characteristics of the powders determine the "flow factor" which may be defined as the weight of powder which will flow through an orifice of given diameter in one minute. This characteristic is of special importance where the pressing operation is carried out automatically, and the dies must be filled by the flow of powder from a hopper. Flow meters are also employed to determine the speed with which a certain weight of powder will travel in specially constructed equipment. Finally, it may be stated that in the case of any given application of powder metallurgy, either all or most of the following properties must be taken into account and held under control: Particle size, particle size range, apparent density, flow factor, shape of particle, cohesive ability, chemical purity, and oxide content.

Mixing of Powder—Where a pure metal is under production this operation is not necessary except in cases where it is desirable to mix together lots of powder having different mesh sizes. The powders are usually mixed in tumblers or ball mills and in some instances the operation is carried out in the presence of a reducing gas to prevent oxidation. Where the specific gravity of the various components of a mixture are quite different, this operation must be carried out in such a way as to produce the greatest possible homogeneity. The time required may vary from a few minutes to as much as 24 hr., or in the case of hard carbide compositions where a grinding operation is also involved, to a number of days.

Compression—The powders may be pressed either hot or cold, but in the majority of cases the operation is carried out at room temperatures. The powder is pressed in dies made of hardened steel, selected to have as low a coefficient of friction as possible. In some cases where small pieces are pressed from highly abrasive powders, the dies are made of hard carbide compositions. The depth of the die will depend to a certain extent upon the compression ratio of the powder, and this is usually in the neighborhood of 3 to 1. In some cases where fine powders are used, the compression ratio may be as high as 6 to 1, or even 8 to 1. The presses employed may be of the hydraulic, cam, friction or knuckle type, and may be equipped with single or multiple dies. As a rule, the pressures employed vary between 5 and 100 tons per sq.in.

The pressing operation may appear quite simple yet it may become troublesome in certain cases. Dies should be made with a high degree of precision and in a great many cases a die with a slight taper will be of great advantage as the amount of pressure needed to eject the compressed piece is in this case only a small part of the pressure exerted in compression. The presses which are now used on mass production are cam presses, friction presses, and hydraulic presses. In the case of hydraulic presses it was found that the slow compression and the pumping operation added to the difficulties and created slipping and entrapped air. A number of hydraulic presses are now built which work with a double reservoir or accumulator and give a rapid stroke allowing 20 and 30 cycles per min. The difficulties which were formerly experienced due to the differential of density of the compressed parts have been largely overcome. Presses and dies are now built in such a way that the percentage difference in density is reduced to nonobjectionable values.

Heat Treatment—Except where this is done simultaneously with the pressing operation, the pressed pieces are given an appropriate heat treatment. This may be carried out in furnaces having an inert atmosphere or in a neutral or reducing gas, or in vacuum. The temperature employed is determined by the metals under treatment and by the characteristics desired in the finished product. In the case of pure metals and in many combinations of metals no part of the material is melted during this heat treatment. In some cases, however, where a small amount of relatively low melting point metal is used in conjunction with a high melting point metal, the lower melting point metal may be fused. This occurs during the heat treatment of hard carbide compositions.

No fixed rule can be laid down as to the temperature to be employed in the treatment of alloys. In general, the temperature used in such cases is about two thirds

that of the melting point of the alloy. In the case of pure refractory metals which are usually heated by the passage of an electric current through the pressed bars, the temperature at the core of the bar is brought close to the melting point of the metal.

Many things may take place during this heat treating operation. Gas may be absorbed or eliminated. Oxide impurities may be reduced. Diffusion of one metal into another may occur and grain growth take place to an extent depending upon the nature of the metal and the temperature employed, and the duration of the heat treatment.

The residual porosity in the heat treated specimens depends largely upon the nature of the material used and the physical characteristics and the chemical purity of the powder. The amount of porosity can be determined approximately by comparing the density of the material with that of the same material in the cast or highly worked condition. In many cases it is desirable to reduce the porosity as far as possible. There are cases, however, where porosity is desirable and is intentionally created within the heat treated specimens. This applies particularly to the so-called oil-less bearings which are produced by the methods of powder metallurgy. Porosity is insured in this material by mixing with the powder volatile salts or low boiling point metals which evaporate on heat treatment, leaving the space they occupy as pores, and if properly carried out, the porosity will be interlocking in nature.

Final Treatment—In some cases the heat treated objects will be the final product. In other cases the material is machined to size or may be subjected to a compression or coining operation to increase the accuracy of the dimensions and improve the surface structure of the metal. In other cases the method produces heat treated ingots, which are subjected to the same mechanical operations that would be used in the case of cast materials.

Hydrometers*

Baumé Hydrometers—For liquids heavier than water—This hydrometer was originally based on the density of a 10% sodium chloride solution which was given the value of 10° and the density of pure water which was given the value of 0°; the interval between these two values was divided into 10 equal parts. Other reference points have been taken with the result that so much confusion exists that there are about 36 different scales in use, many of which are incorrect. In general a Baumé hydrometer should have inscribed on it the temperature at which it was calibrated and also the temperature of the water used in relating the density to a specific gravity. The following expression gives the relation between the specific gravity and several of the Baumé scales:

$$\text{Specific gravity} = \frac{m}{m - \text{Baumé}}$$

$m = 145$ at 60°/60°F. (15.56°C.) for the American Scale

$m = 144$ for the old scale used in Holland

$m = 146.3$ at 15°C. for the Gerlach Scale

$m = 144.3$ at 15°C. for the Rational Scale generally used in Germany

Also see the table for conversion to density and Twaddell Scale.

For Liquids Lighter Than Water—Originally the density of a solution of 1 gram of sodium chloride in 9 grams of water at 12.5°C. was given a value of 0° Baumé and pure water a value of 10° Baumé. The scale between these points was divided into ten equal parts and these divisions were repeated throughout the scale giving a relation which could be expressed by the formula: Specific gravity = $145.88 \div (135.88 + \text{Bé.})$, which is approximately equal to $146 \div (136 + \text{Bé.})$ Other scales have since come into more general use, such as that of the Bu. of Standards, in which the specific gravity at 60°/60°F. = $140 \div (130 + \text{Bé.})$ and that of the American Petroleum Institute (A.P.I. Scale) in which the specific gravity at 60°/60°F. = $141.5 \div (131.5 + \text{Bé.})$.

Twaddell Hydrometer—This hydrometer, which is used only for liquids heavier than water, has a scale such that when the reading is multiplied by 5 and added to 1000 the resulting number is the specific gravity with reference to water as 1000. To convert specific gravity at 60°/60°F. to Twaddell degrees, take the decimal portion of the specific gravity value and multiply it by 200; thus a specific gravity of 1.032 = $0.032 \times 200 = 6.4^\circ$ Twaddell. Also see the table for conversion to density and Baumé scale.

Hydrometer Conversion Tables

This table gives the relation between density (cgs.) and degrees on the Baumé and Twaddell scales. The Twaddell scale is never used for densities less than unity.

Brinell Hardness Test

Preparation of Samples—The surface of all Brinell hardness samples should be flat and reasonably free from scratches. Tests should be taken at a sufficient depth to be representative of the material, or, in the case of large heat treated sections, at such a depth as is representative of a particular zone in the steel.

Ball Diameters and Loads—The diameter of the ball is 10 mm. \pm 0.0025 mm. The weight applied to steels is 3000 kg. for 30 sec.; the weight for softer metals (brasses and bronzes) is 500 kg. for 60 sec. The sample under test should be firmly supported in such a way that the weight acts in a plane normal to the specimen.

Measurements—The diameter of impression used is the average of two measurements at right angles to each other, and the reading error of the instrument should not be more than 0.02 mm.

Formula for Brinell Hardness Numbers—The Brinell hardness number is calculated from the formula as follows:

$$H = \frac{P}{\frac{\pi D}{2} (D - \sqrt{D^2 - d^2})}$$

H = the Brinell hardness number, P = load applied, D = diameter of ball, d = the diameter of the ball impression.

Special Precautions—The Brinell test should not be used on samples of soft steel which are less than about $\frac{1}{2}$ in. thick or on samples so small as to allow flow of metal at the edges as a result of the ball impression.

As there may be some sticking of the mechanism in the hydraulic, hand operated machine, the pumping should be done more slowly as the maximum load of 3000 kg. is approached, otherwise the pressure may go over the load.

Brinell Hardness Numbers—A table of Brinell hardness numbers is given on the next page.

Comparison of Hardness Values—For a comparison of hardness values see the article given at the end of this section entitled "Hardness Conversion Table."

Rockwell Hardness Test

By A. L. Davis*

Principle of Test—Under certain fixed conditions of load the Rockwell tester measures the depth of residual penetration by a steel ball or a diamond cone. The hardness is expressed as a number which is derived by subtracting the penetration from an arbitrary constant. A minor load of 10 kg. is first applied, which seats the penetrator in the surface of the specimen and holds it in position. The dial is then set at the point marked "Set" and the major load applied. After the pointer comes to rest, the major load is removed, leaving the minor load still on.

As Rockwell hardness numbers are based on the difference between the depths of penetration at major and minor load, it will be evident that the greater this difference, the less the hardness number, and the softer the material. This difference is automatically registered when the major load is released (the minor load still being applied), by a reversed scale on the indicator dial, which thus reads directly Rockwell hardness numbers.

Preparation of Surfaces—Surfaces that are ridged perceptibly to the eye by rough grinding or coarse machining offer unequal support to the penetrator. The degree of surface refinement depends on the accuracy required. When testing bar stock or forgings, it is advisable to remove enough of the surface by grinding or machining so that the penetrator will test the true metal underneath. A fairly smooth surface is necessary for accurate work, so the scale resulting from hardening should always be removed before testing. This is particularly true with tool work, as it is often necessary to polish the work with a piece of emery cloth before the proper reading can be obtained.

Thickness of Specimens—For accurate results, the specimen must be of such thickness that the undersurface of the specimen, after testing, does not show a perceptible impression. This thickness will vary greatly according to the hardness of the material tested. The hardest steels give true hardness readings if over 0.027 in. in thickness. Soft material requires greater thickness of specimen, or lighter load, or both.

Curved Surfaces—Results from tests on a curved surface may be in error and should not be reported without stating the radius of curvature. In testing rounds,

Table I
Rockwell Scales

*Prepared for the Hardness Testing Committee by A. L. Davis, Research Engineer, Scovill Mfg. Co., Waterbury, Conn.

The membership of the Committee was as follows: H. M. German, Chairman; C. H. Bierbaum, O. W. Boston, R. C. Brumfield, I. H. Cowdrey, A. L. Davis, and S. L. Goodale.

This article not revised for this edition.

the effect of curvature may be eliminated by filing a small flat spot on the specimen.

Recording Readings and Speed of Machine—Every report of a test made on the Rockwell machine must state what scale is used, or its meaning becomes a matter of guesswork. This is done by the use of the designating letter, such as "B," "C."

Fig. 1 shows the approximate relation between Rockwell scales. These curves are correct only for the kinds of metal indicated in Table I and must not be regarded as holding true indiscriminately.

The machine is provided with means for regulating the rate of application of the load, for which the standard speed is 5 sec. when using the 100 kg. load, and 4 sec. with the 150 kg. load. Metals that flow readily under pressure, such as zinc, should be tested under a specified period of time of load application, which should be stated in reporting the results.

Fig. 1—Approximate relation between Rockwell scales.

Standardization—Standardization of Rockwell machines is secured through the use of standard test blocks obtained from the manufacturer. The machine should check correctly with the standard blocks before being used to test other material. Even when checking satisfactorily with the standard blocks, high readings may yet result if the specimen is placed so that the penetrator strikes upon a spot previously tested. Low results may be obtained when testing thin specimens upon a hollow anvil (that is, an anvil which has been indented while testing very thin specimens or through other abuse). Specimens that are too thin may give either high or low results (though more frequently high) and a rough or corrugated surface will give inaccurate readings.

When testing even thick specimens with rough surfaces, low readings may result due to surface irregularities of the specimen on the face which rests against the anvil. It is almost as important to have this face free from rough grinding-marks and their irregularities as it is the face being tested.

Homogeneity of Specimens—The Rockwell tester measures the hardness of the specimen at the point of penetration, but the reading is also influenced by the hardness of the material under the impression. For example, in testing the hardness of carbon steels (using cone penetrator) the actual depth of penetration is about 0.0027 in., while the effects of penetration extend about 10 times this depth, or 0.027 in., so if a softer layer is located within this depth the impression will be deeper and the apparent hardness less. Therefore, due regard for this condition must be had when testing material with a superficial hardness, such as case hardened work.

To secure the average hardness of materials such as cast iron with graphite particles, or some nonferrous metals whose crystalline aggregates are greater than the area of the penetrator, a penetrator of sufficient size may be used to overcome the local or grain hardness.

Comparison of Hardness Values—For a comparison of hardness values see the article given at the end of this section entitled "Rockwell, Scleroscope, Brinell Conversion Table" and also the curves given at the end of this section entitled "Comparison of Hardness Values."

Precautions

1. As vibrations cause fluctuations in the readings, a location should be selected where there is freedom from vibration. The heavy jars from steam hammers are especially to be avoided.
2. Be careful not to damage the penetrator or the anvil by forcing them together when a specimen is not in the machine.
3. If the anvil has been indented by contact with the penetrator, the readings on thin specimens will be inaccurate.
4. Apply the minor load carefully so as not to overshoot the mark. If the specimen is raised so as to start to pick up the major load, the test should be abandoned and a new one made.
5. The loading lever should be brought back gently, not with a jerk.
6. If the specimen is so thin that there is a perceptible imprint on the back after testing, the hardness shown is not reliable, although sometimes of use for comparison of metal of same thickness.
7. Check the machine regularly every day by use of standard blocks, and record the results for reference.
8. If the test is used on case hardened steel, the accurate hardness is not shown unless the hard layer is at least 0.027 in. thick.
9. The plunger of the dial gage must move with absolute freedom. Erratic results may be due to its binding, either sidewise or back and forth.
10. If the bearing screw in the top lever becomes indented by the ball which presses against it, the results will be erratic. In such a case, the screw should be replaced. The new style (floating cap) index screws are constructed upon a new principle. They are supposed never to require replacement.
11. The ball penetrator tends to become flattened by use, especially in testing hardened steels. It should therefore be checked occasionally and replaced when necessary. In the same way the cone penetrator should be examined carefully if results do not check, and should be replaced if found to be blunted or chipped.
12. The rate of load application is adjustable, and should be so adjusted that when no specimen is in the machine, at least 5 sec. are consumed in the travel of the weight from its initial to its final position, using the 100 kg. load. If the 150 kg. load is used, the time should be 4 sec. as a minimum. The time in actual operation of the machine will be more than 4 sec., because of the added resistance of the test piece; and the time required for the pointer to come to rest will vary from 3 sec. on fully hardened steel to 8 sec. on fully annealed brass. With the softer nonferrous metals, normal indentation by the penetrator is followed by flow or "creep," which results in low readings. Hence the major load should be removed as soon as the pointer visibly comes to rest.

Superficial Hardness Tester—The Rockwell Superficial Hardness Tester is intended exclusively for hardness tests where only very shallow penetration is possible and to determine the hardness of the specimen close to the surface. It is used for testing nitrided steel, safety razor blades, lightly carburized work, brass, bronze, and sheet steel.

Principle of Operation—Instead of the 10 kg. minor load and the 60, 100, and 150 kg. major loads of the regular Rockwell, the "Superficial" applies a minor load of 3 kg. and major loads of 15, 30, and 45 kg.

Penetrators—The regular $\frac{1}{8}$ in. dia. steel ball penetrator is used in the Superficial tester on brass, bronze, and unhardened steel, and it is designated as T. On hard steel surfaces (nitrided steels) the sphero-conical diamond Brale is used and is designated as N.

Designation of Readings—The readings are recorded by giving the major load which is followed by the designation for the penetrator used (N for the diamond Brale penetrator and T for the $\frac{1}{8}$ in. ball penetrator). This is followed by the dial reading. The established prefix symbols are as follows:

Brale N	$\frac{1}{8}$ " Ball
15-N	15-T
30-N	30-T
45-N	45-T

The scale pan applies 15 kg. major load and each of the weights 15 kg., so the major load may be 15, 30, or 45 kg.

Precautions—Although not necessarily polished, the specimens to be tested on the Rockwell Superficial must have a smooth finish. There must be no dust, scale or any particles on the under surface of the specimen or on the anvil, because any sinking of the specimen when under the testing load will add to the actual penetration as measured by the dial gage.

Scleroscope Hardness Test

The principle employed in the scleroscope is the drop and rebound of a diamond tipped hammer. This hammer drops by the force of its own gravity from a fixed height upon the test specimen. The resulting rebound, of the model "C" instrument, is then read against a graduated scale.

The scale consists of units which are determined by dividing the average rebound from quenched high carbon steels into 100 equal parts.

With the model "D" instrument, the readings are recorded on a dial after the strike and rebound of the hammer. The dial hand remains fixed indefinitely or until released for another test.

The scleroscope should always set level when taking a reading, as indicated by the bob rod on the side of the tube barrel. When the instrument is on its clamping stand it is levelled by the tripod screw. When on the swing arm and while using free handed it is levelled by the aid of the plumb bob.

The instrument in addition to setting level should be held steady or free from lateral movement or shocks. When the instrument is moved or shaken roughly enough to rattle the plumb bob it has a marked effect upon the accuracy. These conditions should be observed when free hand tests are made; otherwise, the reading will be low.

Surface of the Specimens—The specimen to be tested, especially when the reading is high, should always have a smooth surface. The higher the readings, the smoother must be the surface. The principal objection to a rough surface is the fluctuation caused in the reading. The reading taken from a rough surface will be lower than the true result.

The surface obtained by using a medium fine emery wheel is usually satisfactory for hard metals, and the surface obtained with a No. 2 or No. 3 file for soft metals will be smooth enough. Mill scale, blister, rust, and decarburization should, of course, always be removed by grinding. The preparation of hardened specimens by grinding, especially with a fine emery wheel, should be done carefully to prevent tempering the surface.

Reading the Scleroscope—The reading is the height of the first rebound noted on the scale at the top of the hammer.

To locate the range, look for the rebound when hardened steel is tested between 90-100; for medium hard around 50, and for soft metals around 10 or 15, and so on. When the range is found, do not look above the range, but rather, a few points below, for if the rebound is higher it is easily determined, but if it is less it will not come within the range of focused vision and will be missed.

The light should fall downward on the instrument so that the glistening on the top of the hammer will act as a guide, and the top of the hammer should be kept bright, as this aids materially in the ease of reading the rebound. A strong light is recommended, either artificial or daylight.

The Hammer Diamond—The hammer diamond of the instrument should be tested regularly on standard blocks. It is advisable to check the instrument in the range in which it is to be used, because sometimes an instrument may read correctly at one hardness and incorrectly at another. If it reads low, particularly on a hard standard block, it is due either to a roughened or worn point. The diamonds are not polished but are reasonably smooth. A magnifying glass will disclose whether the failure to check is due to the condition of the diamond or to some other cause.

The Magnifier Hammer—The regular hammer when used on very soft metals has a comparatively limited rebound. The magnifier hammer is made with a larger point area, which enables it to rebound higher, thus magnifying small but significant variations in readings. This is a special hammer and is more of a laboratory convenience.

The Lens and Pointer Needle—The scleroscope is provided with a lens and a pointer needle which together may be adjusted to any part of the scale. By setting the lens and the needle at the figure that the first rebound shows, slight variations above and below are easily noted. The lens is used principally on soft metals.

The Sound of the Hammer—A little practice will soon disclose, when light or under-weight specimens are tested under the scleroscope, that two different sounds

may be produced. A solid dull thud indicates that the specimen has been clamped solidly and the test is perfect. A hollow ringing or jingling sound indicates that the specimen is either not properly supported, due to excessive warping or lack of parallelness, or, if straight, is not properly clamped. In these instances, the test is useless and should be corrected.

Small and Thin Specimens—Under-weight samples, such as sheets, thin flats, small balls, rods or wire, that can be made to lie flat under the drop hammer, should be clamped down to make certain that no air space or intervention of dirt may cause a variation in the accuracy.

Large or Over-Weight Masses—Large masses to be tested are easier to mount and depend less on the scleroscope anvil for their under support. Accurate results are obtained without clamping large specimens but by placing them on an iron bench plate when testing.

Testing Near the Edge—On small specimens little or no difference is noted by testing near the edge, if the specimens are flat and clamped rigidly. On other shapes, such as cylindrical specimens, particularly when hollow, a certain amount of drop in the reading is noted, due to the lack of mass and improper under support. These errors can be corrected by the use of suitable clamping devices.

Precautions

1. Do not allow the hammer to strike more than once on the same spot or too near it, because the readings will be of no value.
2. Mount specimens as solidly as possible.
3. Testings of small pieces are best conducted in a bench vise by using the swing arm. Use soft steel copper or lead jaws whenever possible.
4. Average readings should be taken in all cases where local characteristics are not being studied.
5. The operating mechanism should be properly lubricated with a light, high grade oil. On the bulb machine no oil should be permitted to enter the glass tube. With the dial machine oil must be kept away from the clutch mechanism.
6. The hammer should fit in the tube properly.
7. Keep the instrument clean at all times.

Low Readings May Be Due:

1. To friction from dirt in the glass or on the hammer.
2. To clogging the vent holes in the bottom cap of the barrel which causes interference with escape of air under the falling hammer.
3. To a loose diamond. (This may be determined under a magnifying glass by tapping the stone lightly.)
4. To being out of plumb.
5. To striking a glancing blow when impacted surface is not level.

High Readings May Be Caused:

1. Under exceptional conditions by wear on the diamond point. Hammers that read too high should be redressed and restandardized. This can be determined by use of standard blocks.
2. When the valve ball becomes clogged with dust so that it cannot set properly some air will enter the glass tube chamber, which causes the hammer to drop with a greater velocity, with the result that abnormally high readings will be obtained.

Comparison of Hardness Values—For a comparison of hardness values see the article on Hardness Conversion.

The Monotron Hardness Test

By O. W. Boston*

Description—The monotron is a hardness testing machine which registers on a dial the load required to produce a definite penetration of a body.

Two indicating dial gages are used, one for measuring the pressure and the other for measuring the depth of penetration in both soft and hard materials.

Principle of Test—Penetration is first made to a predetermined standard depth by aid of a compensated depth micrometer indicator. The hardness number is then read from the pressure scale in terms of kg. per unit area while the load is still on. This feature serves to eliminate errors caused by confusion with elastic recovery and provides for testing other materials in addition to metals.

Upon releasing the load, the depth indicator returns toward zero to the extent of the elastic recovery of the test specimen. The remaining divisions above zero indicate the degree of permanent deformation. By exceeding the recommended standard depth of penetration, ductility and point of plastic flow of metals and compositions are determined.¹ The effect of time is of importance here and is also readily observed.

Preparation of Surfaces—In the use of the standard spherical impresser points, the surface may be either prepared or unprepared.

On prepared surfaces (not polished) the hardness test is made without the use of prepressure, so the pressure indicator hand normally rests at zero. The zero for the pressure scale is really $\frac{1}{2}$ kg. above to offset the weight of the pressure bar. Impressions thus made to the adopted standard depth of penetration, $9/5,000$ in. may be checked up when desired for diameter with a measuring microscope to test the accuracy or adjustment of the machine.

Testing on unprepared surfaces, such as when scaly, rough, or decarburized, may be done with accuracy by the use of prepressure, such as setting the starting point of the pressure hand from 10-20 kg. or more below zero, thus cutting through the irregular surface. When the pressure hand has been brought to zero, the depth indicator hand is then required to penetrate further to the standard testing depth of $9/5,000$ in. and the unit pressure above zero on the pressure scale is taken as the quantitative hardness of the specimen.

Tests on Thin Specimens or Finished Surfaces—When testing sheet a minimum thickness of 0.020 in. is required to give hardness values without anvil effect. Sheets down to 0.010 in. in thickness may be tested although an allowance has to be made for anvil effect. On thinner specimens it is necessary to pile up sheets to make up the required thickness of 0.020 in.

When the test must be substantially nondestructive, only part of the standard penetration is taken, such as $\frac{1}{2}$, in which case the pressure readings are multiplied by three to obtain the full depth values and standard hardness numbers.

Tests on Nitrided Steels—When the case of nitrided steels is of insufficient thickness to permit the application of the fixed load the hardness measurement may be accomplished by taking the sum of three readings of three divisions each, rather than a single reading of $9/5,000$ in.

Monotron Scales—The standard test is made with the diamond ball impresser which is $\frac{1}{2}$ mm. in dia. and penetrates to a depth of $9/5,000$ in.; with this is used scale M-1, which reads directly in Brinell numbers. This test measures the hardness of all metals from the softest to the hardest, including nitrided surfaces and

*Prepared for the Hardness Testing Committee by Prof. O. W. Boston, University of Michigan, Ann Arbor, Mich.

The personnel of the Hardness Testing Committee is as follows: H. M. German, Chairman; C. H. Bierbaum, O. W. Boston, R. C. Brumfield, I. H. Cowdrey, A. L. Davis, and S. L. Goodale.

¹By point of plastic flow is meant the degree of overload under a hardness test penetrator which would cause additional penetration without additional load if extra time is allowed.

By compositions is meant some nonmetallic materials which, when submitted to penetrational strains, will flow when stressed beyond the elastic limit in proportion to the time allowed, something like, but more exaggerated than in metals.

This article not revised for this edition.

cemented tungsten carbide, without any special compensative adjustment of the machine or changing of points.

The term "Monotron Hardness" indicates that the $\frac{1}{4}$ mm. dia. diamond point was used. It is designated as 100 kg. Monotron, or Monotron Diamond Brinell. Larger spherical penetrators are used in dead soft metals because the $\frac{1}{4}$ mm. dia. diamond necessarily gives small values. Hence $\frac{1}{8}$ in. and $2\frac{1}{2}$ mm. dia. cemented tungsten carbide points are used for these metals. Results from these tests are referred to as scales M-3 and M-4 respectively. Scale M-2, using a 1 mm. diamond ball, is not in common use. To penetrate hard metals, a point of this size is too large.

Comparison of Hardness Values—For a comparison of hardness values see the article given on this subject at the end of this section.

Vickers Diamond Pyramid Hardness Test

By S. L. Goodale,* B. B. Rosenbaum,* and Howard Scott†

Principle—The principles involved in testing hardness by the Vickers diamond pyramid and the Brinell methods are practically identical. A predetermined load is impressed at a point upon the specimen. The ratio of the impressed load to the area of the resulting indentation gives the hardness number. The loaded indenter point is lowered upon the specimen gradually, and at a diminishing rate. This application and the removal of the load, after a predetermined interval, are controlled automatically.

Vickers Indenter—As the Vickers indenter is a diamond, it can be used in testing the hardest steels and remains practically undeformed.

The diamond indenter is accurately cut and polished to the shape of a square-based pyramid. Therefore, the impressions are extremely well defined and geometrically similar, irrespective of depth. Although a similar effect can be obtained by use of a conical indenter, the square impression of the pyramid is much more easily measured (across the diagonals) than the diameter of a circular impression.

The surface for testing must be flat and well polished, as scratches or grooves may cause difficulty in reading due to defective corners in the impression.

Measurements—The measurements are taken by means of a specially constructed ocular micrometer which is fitted with knife edges rather than the usual hair lines. The readings are taken from actual figures at the side of the ocular, thus eliminating the possible error of miscounting the divisions on a small scale.

Application of Load—The internal mechanism of the Vickers instrument consists mainly of a weight operated cam. The speed of rotation of this cam is controlled by an oil dashpot, and the movement applies the load to the diamond indenter. The same cam applies, removes, and controls the duration of the load. The load is light, varying from 1-120 kg. according to requirements. It is applied and removed automatically. One movement of a starting handle releases the mechanism, and the depression of a foot pedal restores it to its original position. An audible click informs the operator of the duration of the test. It is recommended that the time of load application be standardized at 10 sec.

Upon lowering the stage, the microscope may be swung into a position over the impression. The measuring microscope is of the angular type, centers automatically, and is capable of measuring to 0.00005 in.

The Impression—The impression appears as a dark square on a light ground. The measurements are taken across the diagonals of the square between the knife edges in the ocular. There are three knife edges: One is fixed, another movable by means of a micrometer screw connected to the counting mechanism, and the third provided for rapid readings to specified limits. The left hand corner of the impression is set to correspond to the fixed knife edge, the movable knife edge adjusted to coincide with the right hand corner of the impression, and the reading taken by reference to the indicator at the side of the ocular. The actual hardness figure is then found from a chart or calculated by a simple formula.

Hardness Numbers—Hardness numbers obtained with a pyramid indenter are practically constant, irrespective of the load applied. The Vickers and Brinell hardness values on steel are practically identical up to a hardness of about 300. At higher hardness values the Brinell falls progressively lower than the Vickers number, and is not reliable above about 600 Brinell hardness, even with specially hardened balls. This irregularity is caused by flattening of the steel ball under the heavy local loads required for testing hard materials, whereas the diamond shows no distortion.

*Prepared for the Hardness Testing Subcommittee by Prof. S. L. Goodale and B. B. Rosenbaum, University of Pittsburgh, Pittsburgh, and †Howard Scott, Engineer in Charge of Metallurgical Section, Westinghouse Electric & Mfg. Co., Pittsburgh.

The membership of the subcommittee was as follows: H. M. German, Chairman; C. H. Bierbaum, O. W. Boston, R. C. Brumfield, I. H. Cowdrey, A. L. Davis, and S. L. Goodale.

The relations for slide rule calculation of Vickers hardness are:

$$H = 1.8544 \frac{L}{d^2} \text{ where } H \text{ is the Vickers pyramid numeral; } L \text{ is the load in kg.,}$$

and d is the diagonal of the indentation in mm. d is obtained from the ocular reading, r , from the relation:

$$d = 0.002 r \text{ or } 0.001 r \text{ (for } \frac{2}{3} \text{ in. objective), and}$$

$$d = 0.005 r \text{ or } 0.0025 r \text{ (for } 1\frac{1}{2} \text{ in. objective), depending on the constants of the micrometer ocular.}$$

The hardness numeral is calculated from the ocular reading by the following relation:

$$H = 0.4636 \frac{L}{r^2} \times 10^6 \text{ (for } \frac{2}{3} \text{ in. objective, where } d = 0.002 r);$$

$$H = 1.8544 \frac{L}{r^2} \times 10^6 \text{ (} \frac{2}{3} \text{ in. objective, where } d = 0.001 r);$$

$$H = 0.07418 \frac{L}{r^2} \times 10^6 \text{ (for } 1\frac{1}{2} \text{ in. objective, where } d = 0.005 r);$$

$$H = 0.2967 \frac{L}{r^2} \times 10^6 \text{ (} 1\frac{1}{2} \text{ in. objective, where } d = 0.0025 r).$$

Comparison of Hardness Values—For a comparison of hardness values see the hardness conversion table on page 127.

Testing Thin Sheet—This tester can be used on thin sheet because of the accuracy with which the small impressions may be read. Lighter loads are used when testing sheet thinner than about 25 gage.

Advantages—Some of the advantages claimed for the Vickers machine are:

1. The load is uniform, and automatically applied, so that there is no inertia.
2. The duration of the load is uniform, the load being automatically removed at the end of a predetermined interval.
3. The hardest material can be tested accurately because of the diamond indenter.
4. There is very little damage done to the specimen because the impression is very small.
5. Both the "case" and "core" of case hardened steels may be tested, since the impression is only about 0.002 in. deep on hard steels.
6. Only slight resetting is necessary under the microscope.
7. Errors in reading are greatly eliminated, since readings are taken from actual figures rather than from a scale.
8. Specimens with a wide range of sizes can be tested. Specimens up to 13 in. deep, in some cases 17 in., can be accommodated under the indenter.

Disadvantages—A disadvantage attributed to the Vickers machine is that it is more of a laboratory instrument than a shop machine. Strictly speaking, this is not true, for the construction is sturdy, and the operation simple. As the impressions are much smaller than for the Brinell or Rockwell machines, the *surfaces for testing must be prepared much more carefully*. Although the Vickers instrument is definitely a machine of precision, it requires *care* in operation rather than any particular *skill*.

Checking—It is advisable to check the machine occasionally against standard test blocks. In case of failure to check satisfactorily, the trouble may be due to the plunger sticking in the sleeve. Polish the tube or plunger carrying the diamond indenter in a longitudinal direction with dry emery paper (400 C).

Precautions—

1. Apply test only to smooth level surfaces representative of the material.
2. Select the load with regard to hardness and thickness of the piece to be tested.
3. Replace the diamond when it becomes chipped as shown by irregularity of the impression made.
4. Check the zero position of the micrometer occasionally.
5. Adjust the knife edges of micrometer accurately perpendicular to the impression diagonals.
6. Keep the dashpot full of suitable oil to prevent impact loading.
7. Discard readings made on a tilted surface which are indicated by a large difference between the two diagonal readings

The Microcharacter

By C. H. Bierbaum*

Introduction—The Microcharacter offers a method for testing the hardness of microscopic areas or constituents of alloys, exceedingly thin layers of metal, and gradients of hardness.¹ The degree of refinement of this method has been made possible only by the skill of a lapidary, F. F. Gilmore of Boston, who now grinds the diamond to a degree of refinement never heretofore attained. The sapphire was first used, but was found unsatisfactory. The instrument was originally designed for studying bearing alloys;² but now finds general application.

Description—The test specimen must be small (not in excess 1 sq. in. of area). It should have a ground and polished metallographic surface. The specimen should be mounted on an ordinary microscope slide with plastic material in the usual manner. The microscope equipment should be rigid and of the highest order, a 1.5 or 2 mm. oil immersion and a 3 or 4 mm. dry objectives should be provided, also a filar screw micrometer ocular of 15 or 25 X. A vertical illuminator giving ample illumination must be provided. The combination should be such that a single micron (1/1000 mm.) can be measured with a reasonable degree of accuracy. The standard load on the diamond is 3 g. The diamond is ground with three facets making right angles with each other, a solid right angle, the corner of a cube. It is mounted so that the diagonal of the cube is normal to the test surface, with one edge accurately in line of cut. The point of the diamond is sharp and perfect under a magnification of 2000 X.

Operation—The ocular should first be calibrated with a stage micrometer, so that the value of the subdivisions of this ocular scale are known in terms of microns.

Microhardness Numbers

Standard 3-g. Weight

$$\kappa = \lambda^{-2} 10^4 = \text{Microhardness}$$

$$\lambda = \text{Width of Microcut in Terms of } \mu$$

¹Trans. A.S.S.T., Jan., 1931.

²Trans. A.S.M.E., 1920, p. 1099.

This article not revised for this edition.

The mounted test specimen is then placed on the instrument. A drop of "super-fine" watch oil (can be obtained in the jewelry trade) is placed upon the test surface at the point where the microcut is to begin. The diamond is then lowered upon the test piece into the drop of oil until the suspension arm is horizontal as indicated by its spirit level. The worm gear is then engaged and the test surface slowly moved under the diamond point, making the microcut. After the lubricating oil has been removed and immersion oil applied to the test surface, the width of cut is then examined and measured at points of interest and translated into micro-hardness according to the accompanying formula and table.

Caution—The diamond, the hardest of all known substances, is brittle. Under no conditions should the point of this diamond be brought in contact with another diamond, since an almost insensible pressure upon this exceedingly sharp point produces a load per unit area that is far in excess of the crushing strength of the diamond. It should not be subject to blows of any kind during manipulations. The instrument is not intended for commercial testing; it is for research only, in the hands of a skilled metallurgist or microscopist.

File Hardness Test

By H. T. Morton*

The File Test—To determine whether or not a steel article is "file hard," the handle of the file is grasped in the right hand with index finger extended along the file, and the surface to be tested rubbed slowly but firmly with the sharp teeth. Just as soon as it is apparent whether or not the file will bite, it is removed. The object to be tested may be held in the left hand and rested on a bench or against a stop, or it may be clamped in a vise.

The simplicity and rapidity of this method of hardness testing are strongly in its favor for the control of hard surfaces in production. In the period of a few seconds the tester can determine the hardness of each tooth of a gear, various surfaces of a ball or bearing, or other hardened parts without injury to the surface.

File Hardness or "Scratchhardness"—It has been suggested that the ability to resist a file be called the "filehardness" of a surface. There are grounds for the belief that the degree of filehardness is related to the ability to resist wear and abrasion, for when the file tooth takes hold of the metal it penetrates to a small degree, as well as scrapes and wears away a small portion of the metal—that is, it "abrades" it. This is probably a better approximation for gears and other articles which get a sliding or rubbing action than for cutting tools. Some cutting tools give excellent service, even though less than "file hard."

Factors Influencing Test—Comparisons of filehardness are dependent upon three factors: (1) The size, shape, and hardness of the files; (2) the speed of moving the file across the hardened part and the pressure and angle of the file while moving; (3) composition and heat treatment of the steel being tested.

1. *Size, Shape, and Hardness of Files*—The first item can be standardized by using files made especially for testing, and by making sure that the files are not used after they have become dull. Pieces of steel or samples of the product with the proper hardness and temper so they can just be touched with a new file can be used as gages or master test pieces for the beginner, and later for comparison tests when any doubt exists as to the hardness of the article or the cutting ability of the file. As long as the file will cut the master test piece, it is good to use for testing purposes. The number of times a "single spot" on the file can be used will depend upon the hardness of the articles being tested and the degree of skill acquired by the workmen, but there is always the master test piece to prove the accuracy and cutting ability of the "single spot."

New files to be used for testing should be standard (that is, able to cut a standard hardness block) and uniform (that is, every spot on every file able to cut the block). Such files are procurable from reputable manufacturers.

One manufacturer recommends 10-in. mill bastard files for testing. Another makes the following grades of testing files and describes their uses as follows:

- 6-In. Pillar Testing File No. 0
- 6-In. Pillar Testing File No. 1
- 8-In. Pillar Narrow Testing File
- 6-In. Three-Square Testing File No. 1, ▲

"The pillar type of file is used for testing hardened or tempered steel articles of flat, oblong or square shape, and also the outside surface of round or curve-shaped articles. The 3-square type is used for testing articles which are irregular in shape, and in which there are crevices or grooves. The 8-in. pillar narrow testing file and the 6-in. No. 0 file are better used when testing for absolute hardness, while the finer No. 1 cut is better for use when testing tempered articles."

2. *Speed, Pressure, and Angle of File While Making Test*—The second item influencing the file test is controlled by the skill of the workman. The slower the speed the more accurate is the test, because high speeds will wear off the surface of both the part and the file, thereby giving a false indication of softness. A girl in inspection was able to wear away hardened balls (Rockwell C-64) by moving the file fast enough, while a man applying a heavy pressure at slow speed produced a negligible effect on the same material.

*Metallurgist, Hoover Ball and Bearing Co., Ann Arbor, Mich.

Shape of the article and angle of contact with the file teeth also influence filehardness. It is easier to "touch" a narrow edge than a wide surface. There is also a noticeable difference in resistance given by a polished piece as compared to a rough surface, and by a dry surface as compared to one wet with oil. Even so, there is seldom any necessity to prepare the surface to be tested, such as by removing all scale; generally the file will remove enough scale to give an accurate test of hardness, provided the part is held rigidly.

3. *Influence of Composition and Heat Treatment*—The third item, namely the composition of steel and its heat treatment, is such that the file is limited to certain very high hardness values, with a minimum of approximately Rockwell C-58-C-60. Its utility on tempered parts might be limited to a still higher range. The writer's experience with standard 10 in. mill bastard files indicates that quenched carbon steel parts of Rockwell C-60 hard will not be cut, while C-58 cuts slowly, and chromium steel parts tempered at 350°F. with a Rockwell of C-62-64 will often cut easily.

A leading American manufacturer states that his files made especially for testing will not cut straight carbon tool steel (Rockwell C-64-C-68) immediately after drastic quenching, but will cut it after tempering to 375°F., even though the Rockwell hardness still measures C-64-C-66.

Soft Spots and Decarburization—For determination of soft areas or depth of decarburization the hardened parts should be clamped in a vise, rather than held in the hand. This insures rigidity and allows the tester to use both hands, and thereby control his applied pressure and speed of stroke in filing away the soft surface metal. Under these conditions the file test is much quicker than microscopic examination or other methods of measuring depth.

Advantage of Test in Hands of Skilled Inspectors—File testing is an art acquired by experience rather than a scientific method. It must be fitted to the needs of the particular product being manufactured and in only a few instances is used as a standard for specifications. The terms of defining it are so flexible, and ordinary files vary so much, that the results are not reproducible enough to be passed between manufacturing plants as a standard. But it can be and is developed in individual factories into an excellent method of determining the hardness of hardened metal products.

The skilled workman who uses a file for testing soon learns to allow for all the factors that might influence the accuracy of the test, and when using standard testing files the file test becomes an extremely useful measure of hardness. The required skill is not difficult to acquire.

Cost of the test is dependent less upon labor costs than upon the life of the files used. When testing parts having narrow contacts with the files, the teeth are worn and broken quickly, thereby allowing only a few strokes to each area on the file, but skilled workmen will be able to use the full width of the file in this manner. For wide specimens the teeth wear more slowly but uniformly, necessitating care in discarding the file when it is too dull for good use.

The rapidity of the file test keeps it as a regular means of testing hardness and decarburization, but it is limited to a small range of usefulness—mostly on hardened parts, not tempered. Whenever it is desired to define the term "file hard," one should specify the hardening procedure on the test block which the file cannot touch.

Hardness Testing at Elevated Temperatures

By Dr. Oscar E. Harder*

Introduction—Methods have been devised and used to determine the hardness of metals and alloys at elevated temperature, but as yet no standard procedure seems to have been adopted. As a result, many of the data reported in the literature are doubtful, and even the best figures available by different investigators are generally not comparable because of the different procedures used in making the tests. This article briefly reviews the methods that have been used in hardness testing at elevated temperatures and discusses the important factors involved and the precautions to be taken in making such tests.

Testing Methods—For convenience, the procedures that have been used in hardness testing at elevated temperatures may be grouped under 4 methods, as indicated below; they are given in about the chronological order in which they were first used:

A. Ordinary Hardness Test—The sample to be tested is heated to the desired temperature, removed from the furnace, and then tested in the usual way. Generally, the Brinell test has been applied. Obviously, the method is open to the criticism that the indenting ball is cold and, therefore, cools the metal at the contact. The specimen cools during testing and at higher temperatures, if a steel ball is used, it may be softened and deformed.

B. Drop or Impact Hardness Test—This method determines the impact hardness (drop hardness) and then either expresses the results as the work divided by the volume of the indentation ($\text{mm. kg.} \div \text{cu.mm.}$) or by reference to a curve, converts these values into equivalent static hardnesses. This method has been rather extensively used, because the time during which the indenter is exposed to the high temperature is reduced to a minimum. Usually, a ball of 5 or 10 mm. dia. has been used as the indenter and the diameter of the impression measured. In some cases a material of known hardness has been placed back of the ball, so that it also showed an impression as a result of the impact, from which the relative hardness could be calculated. This method is open to the objections that the indenter is cold and that impact hardness values may not be directly comparable to static hardness values.

C. Indenter and Specimen Heated—In this method the indenter and the specimen are both heated to the desired temperature and the test made either by the static or impact method. The cemented carbide ball has made it possible to make the ordinary Brinell test at temperatures extending well into the red heat range.

D. Mutual Indentation—This method is the one most recently reported and employs the mutual indentation produced on 2 cylindrical specimens of the material being tested under selected loads. Its advantages in the procedure described are that indentation is made on 2 specimens of the same material held at any desired temperature. Its disadvantages are that special specimens are required, and a factor must be used to convert the hardness values obtained into standard Brinell values. For extremely hard materials, this method has the further disadvantage that the flattened surface is narrow, even when a load of 3,000 kg. is applied, and for that reason sufficiently accurate readings are difficult to make.

The application of the mutual indentation method of hardness testing at ordinary temperatures has been described by Cowdrey,² and its application to determining the hardness of high speed steels and related alloys at elevated temperatures by Harder and Grove.³

Results of Tests—For complete information on the methods of hardness testing at elevated temperatures and a discussion of the results obtained, a selected list of references is given at the end of this article. See especially references 2 and 5.

Critical Discussion of Methods—It seems obvious that method A cannot be depended upon to give an accurate measure of the hardness of materials at elevated temperatures, and it should not be considered as satisfactory.

Method B may give relative values, but the data available indicate that higher hardness values are obtained by this method of testing at elevated temperatures than by either methods C or D. For that reason it seems that a preference must

*Asst. Director, Battelle Memorial Institute, Columbus, O.

This article was not revised for this edition.

be given to methods C and D to obtain reliable hardness values at elevated temperatures. Method C seems preferable in most respects, because the values obtained are expressed in terms that are widely employed without using a conversion factor, as is required in method D. Method C also makes it possible to use a more conventional test specimen.

Indenters—Because the usual steel balls will be softened at the higher testing temperatures and are therefore, likely to be deformed in testing, even when a new ball is used for each test, as was done by d'Arcambal,³ it seems advisable to limit their use to temperatures below which the indenters will be appreciably tempered. This will limit the use of steel indenters to temperatures of about 400-900°F., depending upon the composition and its resistance to tempering on heating. Perhaps steel indenters should be limited to temperatures up to 400°F.

The sintered carbide ball appears to be usable to a much higher temperature, probably up to at least 1475°F. Likewise, the diamond indenter retains its hardness at elevated temperatures and should be usable up to 1500-1800°F.

In method D, the material being tested is used as the indenter, and there seems to be no difficulty about using the elevated temperatures except that the load applied must be decreased as the temperature increases or as the hardness of the material decreases. Apparently, satisfactory results have been obtained up to 1475°F. with the high speed steels.

Method of Heating Specimens—Obviously, it is necessary to heat the specimens under test throughout to the testing temperature and to hold them at this temperature during the test. For the lower temperatures, water, glycerin, cylinder oil, and possibly a fused salt bath may be used. For the higher temperatures, it is more convenient to use some type of furnace, preferably electrically heated, which can be used to maintain accurately the desired temperature.

Effect of Time at Temperature—For temperatures below the annealing or softening temperatures of the material under test, the time that the specimens are held at temperature is of minor importance. As soon as the testing temperature is above the annealing or softening temperature of a material being tested, the holding time becomes important. For example, Wissler and Day¹¹ made tests on a high speed steel of the 18-4-1 type at 1300°F., in which the specimens were held 20 min., 1 hr., and 1½ hr. and obtained the Brinell hardness of 275, 193, and 175, respectively. At 1100°F., in which the holding times were 20 min. and 1½ hr., hardness values of 495 and 415, respectively, were obtained. The effect of holding time at temperature, which has varied considerably with different investigators, is one of the factors that has contributed to the lack of consistent results at the higher testing temperatures.

Two methods of procedure might be considered; first, the material being tested might be thoroughly annealed or tempered at a temperature at least as high as the testing temperature before it is subjected to the hardness test at elevated temperatures. Under this procedure, the holding time would be of minor importance provided the specimen was heated uniformly throughout.

The second procedure would involve heating the specimen only long enough to bring it to the testing temperature and making the test without establishing equilibrium as to tempering or annealing at the testing temperature.

A combination of these two methods might involve holding for relatively long periods of time at the testing temperature in order to approach an equilibrium condition with reference to tempering and annealing, but since these reactions proceed slowly, it would seem that the testing period would be unduly prolonged in this process.

Time of Application of Load—The behavior of the metals in deforming under load at elevated temperature depends upon the individual metals, that is, as to whether or not they work harden to some extent or whether they are automatically annealed as they are deformed. There seems to be no good reason for making the time of application of the load greater than that at ordinary temperatures, and it would seem that satisfactory results should be obtained with the loads applied for an interval of 30-60 sec. as in ordinary testing.

Test Specimens

By R. L. Templin*

Introduction—In the determination of the mechanical properties of metals variations in the testing methods used, may and often do, cause variations in the values obtained. Unfortunately the effects of such variations are quantitatively different for many of the present day commercial metals and alloys. Because of these facts, it has long been recognized, though perhaps not fully appreciated, that quite definite methods of testing must be followed if acceptable results are anticipated. Satisfactory methods of testing for metals must give proper consideration to such factors as selection of test coupons, size and preparation of test specimens, axial and uniform loading of test specimens, speed of testing, sensitivity and accuracy of all testing apparatus used, and calculations, plotting or other interpretations based on observed values.

Fig. 1—Tension test specimen for general use in testing metals.

Fig. 2—Various sizes of threaded end, round tension test specimens for metals.

Mechanical property test values for metals obtained in accordance with the best testing methods now in use are, of necessity, empirical in character but have many useful purposes. Some of the more important fields wherein the mechanical property test data for metals are of importance include: Specifications, manufac-

*Chief Engineer of Tests, Aluminum Co. of America, New Kensington, Pa.

turing process control, basis of engineering design values, development of new alloys or fabrication processes, and as a basis for comparison with other metals.

Tensile Tests—The generally accepted standard specimens for making tensile tests of metals are shown in Fig. 1-8. The round specimen shown in Fig. 1 is the most satisfactory for ordinary testing purposes where the size and shape of the product will permit of its use. When the product to be tested requires the use of a smaller specimen, and comparable data are desired, a geometrically similar specimen should be used. Various sizes of such smaller specimens, with readily usable gage lengths, are shown in Fig. 2. While these specimens are shown with threaded ends, they may be prepared with plain or shouldered ends to suit the testing apparatus available. In all of the round specimens shown in Fig. 1 and 2, the gage length is equal to 4 times the diameter or $4\frac{1}{2}$ times the square root of the cross sectional area of the reduced portion of the specimen.

The rectangular or flat tensile specimens now in general use for metals are shown in Fig. 3 and 4. The length and width of these specimens are maintained constant within the limits shown, irrespective of the thickness of the specimens. This procedure is followed for practical reasons but makes a satisfactory comparison of elongation values quite difficult, when appreciable differences in thickness are involved, or results from the use of both types of specimens. Other factors remaining constant, the elongation of a ductile metal will vary as some function of the cross sectional area of the test specimen used. Consequently the smaller of the two specimens shown will give lower elongation values for any given thickness of metal. Reduction in area values from thin rectangular specimens are usually not reliable or obtainable because of the difficulties contingent upon their measurement.

Despite the difficulties encountered in making elongation or reduction in area comparisons of metals when using the rectangular or flat specimens, the results obtained with these specimens, especially tensile strength, yield strength (or yield point) and elongation, serve a useful purpose in the manufacture, sale, and use of many metal products.

Other standard types of tensile specimens together with their specific fields of use are shown in Fig. 5-8.

Compression Tests—Compression test specimens for metals are not at the present time as standardized, for example, as the tensile specimens. Tentatively, however, three types are recognized as being suitable for metals. These are shown in Fig. 9. The short specimen is used for compression tests of bearing metals, the medium length specimen for determining the general compressive strength properties and the long specimen for determining the modulus of elasticity of metals. The dimensions suggested for general use are as follows:

Specimen	Dia., in.	Length, in
Short	$1\frac{1}{4} \pm 0.01$	1
	0.798 ± 0.01	2%
Medium length	1 ± 0.01	3
	$1\frac{1}{8} \pm 0.01$	3%
Long	$1\frac{1}{4} \pm 0.01$	12%

Compression tests are appreciably more difficult to make, with satisfactory results, using the ordinary type of universal testing machine, than are the tension tests.

This is so because in the compression tests eccentricities in loading tend to increase as the load on the specimen is increased, whereas in the tensile tests the eccentricities tend to decrease under increasing load. This is especially so for loads in the plastic range. In spite of these difficulties, compression tests can be carried out successfully if proper attention is given to details of apparatus and procedure.

Shear Tests—Although a variety of shear tests are made on metal products no generally recognized standard methods or specimens have been adopted. One type of shear test is the torsional in which either a solid or tubular specimen is used. Solid specimens are often tested full size, but for more accurate results they may be reduced in lateral dimensions as in the case of the tensile specimens. The tubular or thin wall, hollow specimens are the more suitable for obtaining shearing strength values for metals, largely because the cross section of the specimen has more nearly uniform stress than in the case of the solid specimen. For ultimate shear strength determinations, the hollow specimens should have short reduced

sections of about $\frac{1}{2}$ diameter, and a diameter to thickness ratio of from 10-12. For determination of shear modulus and yield strength values, a hollow specimen having a length of at least 10 diameters and a ratio of diameter to wall thickness of not over 10, for its reduced section, is to be preferred. The actual dimensions of the specimen used may well be chosen to suit both the size and type of testing machine available, as well as the product to be tested.

Fig. 3—Tension test specimen for plate material ranging in thickness from about $\frac{1}{4}$ - $1\frac{1}{2}$ in. For plate over $1\frac{1}{2}$ in. thick the specimen may be machined to not less than $\frac{1}{4}$ in. thickness or a standard round specimen used.

Fig. 4—Tension test specimen for sheet metals ranging in thickness from about 0.01 to, but not including $\frac{1}{4}$ in.

Fig. 5—Type of tension test specimen particularly adapted to hard steels and brittle materials.

Fig. 6—Tension specimen for metal tubing ranging in size up to about 2 in. outside diameter but particularly for sizes 1 in. outside diameter and less. For larger sizes cut-out specimens as shown in Fig. 4, for thin wall tubes and as shown in Fig. 1 or 2 for thick wall tubes may be used.

Fig. 7—Tension test specimen for malleable iron (not machined).

Fig. 8—Tension test specimens for cast iron. (a) Machined all over from A.S.T.M. arbitration test bar. (b) Cast to size and only the threads machined on the ends.

Fig. 9—Compression test specimens for metals.

Other shear tests, in the case of sheet or plate, are made by suitable punches and dies either fitted directly into a testing machine or in a subpress which can be used in a testing machine, so that the load required to shear a specimen of a given size can be measured. The punches and dies are usually circular and the specimen may be any convenient size and shape so as to permit of a complete disk being punched from it. Yet another form of shear test is made by using 3 ring-like dies with either round or square holes through their axes, so that a specimen of the same shape can be inserted, the outer dies supported and the middle die caused to shear a short section from the specimen by suitable fixture in a testing machine. From such a double shear test the shearing strength is readily obtained.

Impact Tests—Tentative standard methods (A.S.T.M.) are now in use for making single blow impact tests of metals. The types and sizes of specimens recommended by the A.S.T.M. are shown in Fig. 10 and 11. A specimen with a "keyhole" notch, as described in the article on "Notched Bar Testing," page 671, is also used. Unnotched $\frac{1}{4}$ in. sq. specimens have been extensively used for checking nonferrous die cast metals.

Many types of impact tests have been experimented with, and numerous sizes and shapes of specimens have been studied in attempting to develop a satisfactory, so-called "shock resistance" test. This investigational work is still in progress, but so far no one type of test or specimen appears to suit all metals, with the

result that many differences obtain in commercial testing practice. In some applications the impact test has shown considerable merit, while in others the results obtained have been of dubious value at best.

Other forms of the impact test include repeated impact and torsion impact tests, each requiring different sizes of specimens, depending on the testing machine used.

Hardness Tests—The hardness tests require no special size or shape of specimens but there are limitations obtaining which are covered in the sections of this book on the various kinds of hardness tests.

Bend Tests—Tentative standard methods are now in use for determining the cold bend properties of metals. The recommended types of specimen for such tests include both a rectangular

Fig. 10

Fig. 11

Fig. 10—Simple beam (Charpy type) impact specimen.

Fig. 11—Cantilever beam (Izod type) impact specimen.

and a round specimen. The rectangular type is the preferred form, with a width at least three times the thickness. The edges of the specimen are required to be smooth, so that the fracture will not take place at the edges. A radius not greater than $\frac{1}{4}$ the thickness of the specimen is permissible on the edges of the specimen. The length of the specimen is permitted to vary with the thickness, but is considered unimportant provided it is sufficient to permit of performing the bending operation. When round bars or specimens are tested by the recommended method, the results obtained should be considered as comparative only; as for any given material the fiber elongation has been found to vary slightly with the diameter of the test piece.

The gage length over which the elongation is to be measured is specified as 0.3 in. in the case of plate from $\frac{1}{4}$ – $\frac{1}{2}$ in. in thickness and 1 in. for all plates over $\frac{1}{2}$ in. in thickness. The gage length should be located at the section of maximum bending, and in the center third of the width of the specimen. A detailed procedure is outlined in the tentative standard methods of the A.S.T.M. for carrying out bend tests using these types of specimens.

Various other types of cold bend tests are used for different types of metal products. In general such tests are made by bending a strip or piece of the metal around a mandrel or die of specified dimensions, by steady application of load or by hammering until rupture occurs or until an angle of either 90° or 180° is attained. Many forms of cold bend attachments are available for commercial

testing machines as well as machines intended solely for the purpose of making bend tests. Although one of the oldest tests and apparently one of the simplest, yet the results obtained are frequently appreciably affected by the procedure and apparatus used in making the tests.

Fatigue Tests—No standard or tentative standard methods including specimen size and shape, have been generally accepted for making fatigue tests of metals. The rotating-beam type of fatigue test is perhaps the one most generally used. In this test the stress in the outermost fibers of the specimen undergoes a cycle of complete reversal from tension to compression, during each revolution of the specimen. Three types and sizes of specimens in current use are given in the Report of the Research Committee on Fatigue of Metals.* There are many other types of fatigue or repeated stress tests used experimentally and in most instances a different size and type of specimen is used. These tests include those in which the stresses are not completely reversed but vary throughout a given range and those involving combinations of tensile, compressive, or torsional stresses.

Cupping Tests—Cupping tests of sheet metals are used as an index of the ductility and in some instances of the drawability of the material. While they have been used for many years, yet at the present time no generally accepted standard conditions of test have been agreed upon, with the result that the values from different types of machines are not concordant. The specimens used in these tests are usually in the form of disks, squares, or strips of suitable dimensions (about 3 in. dia. or width) to fit into the testing machine, and of the same thickness as the sheet metal they represent.

Fatigue Testing

By R. L. Templin*

For many applications of metallic materials it is necessary to consider not only the static properties of the materials but their resistance to many repetitions of stress as well. The resistance to large numbers of repetitions of stress, or to fatigue, is indicated by means of fatigue tests. Generally, when the fatigue resisting qualities of a material are being considered the property known as the endurance limit is used. Endurance limit is defined as the limiting stress below which the material will withstand without fracture, an indefinitely large number of cycles of completely reversed stress. When cycles of stress other than completely reversed are referred to, suitable qualifying adjectives are used to define the conditions.

Fig. 1—R. R. Moore rotating-beam fatigue machine.

Values of endurance limit are usually obtained by using a machine of the rotating simple beam type, Fig. 1, in which the outermost fibers of a solid cylindrical specimen are subjected to cycles of completely reversed stress from tension to compression^{1,2}

The specimen used in this machine is shown in Fig. 2. Another machine^a of this general type for testing wire and tubing is shown in Fig. 3. This machine can be used for testing long specimens without machining. Rotating cantilever beam machines of the general type of that shown in Fig. 4 are sometimes used, but the type shown in Fig. 1 is more commonly used than either of the others.

Fatigue specimens usually are less than $\frac{1}{4}$ in. in diameter at the reduced section. Tests of sound uniform ferrous materials, however, using 5 different sizes from 0.05-2.00 in. diameters, have indicated that size of specimen has no effect upon results of fatigue tests.⁴ Size does have some effect in materials which are not sound and homogeneous, such as cast metals containing blowholes.⁵

Because the presence of scratches or tool marks on specimens produces stress concentrations which affect the determination of endurance limit (a rough tool finish reducing it as much as 20% below that for suitably polished specimens²), fatigue specimens must be carefully machined. The machining should be done with sharp tools, using light cuts and slow speeds. Circumferential scratches or tool marks are more injurious than are longitudinal ones. The final finish of the reduced diameter part of the specimen should be such that no circumferential scratches can be seen by the unaided eye. For producing the final finish an abrasive material at least as fine as No. 00 emery cloth is required for steel, and still finer for softer metals.

Fig. 2—Specimen for R. R. Moore machine.

*Chief Engineer of Tests, Aluminum Co. of America, New Kensington, Pa.

When the test material is of a form which must be used as fabricated (as, for example, sheet or wire), the specimens should be carefully selected and handled to avoid stress concentrations. In such tests the design of the specimen may be such that part or all of the surface at the critical section is the original surface of the material, without any further preparation.^{2, 3} Obviously, any surface imperfections in the original material should be avoided. The sheet specimens used by some investigators have a narrow critical section, making it very important to avoid any damage whatever in handling.⁴

Repeated stress tests require a comparatively long time to determine endurance limits. For this reason recent investigators have been employing machines which can operate at relatively high speeds. Tests have shown that, in tests of sound materials, no appreciable speed effect occurs at speeds up to 10,000 cycles per min., and at speeds of 30,000 cycles per min. only a small increase in endurance limit is obtained.⁵ The design of the testing machine must be such, however, that undesirable effects of secondary stresses are avoided.

The results of fatigue tests are plotted using semilogarithmic coordinates, with values of stress, S , as ordinates and numbers of cycles, N , as abscissas, as shown in Fig. 5.

The semilogarithmic system is used because it is possible to plot on the same diagram both small and large values of N with the same percentage of accuracy, and because there is less danger of an inaccurate selection of the endurance limit than if Cartesian coordinates were used.

For many steels, the S - N diagrams obtained in this way usually consist of two straight lines, one sloping line and one horizontal, joined by a slightly curved "knee," the position of the horizontal line indicating the endurance limit. In such diagrams the "knee" generally occurs at less than 10,000,000 cycles.

For nonferrous metals, the diagram usually is a curve, with the bottom becoming horizontal or nearly so at the endurance limit. A much larger number of cycles is required in order to determine the endurance limit of such metals, some investigators using a 500,000,000-cycle basis for certain materials.

When using endurance limit data, the number of cycles of stress used as a basis for determining this value should be considered and stated in reporting results.⁶ In foreign literature, endurance

Fig. 4—University of Illinois high speed fatigue machine.

limits of certain metals sometimes are based on 20-50 million cycles. Such values, especially for light alloys, frequently are definitely higher than would be obtained on a 500-million cycle basis.

Because of the time and expense involved in making fatigue tests, various attempts have been made to devise accelerated fatigue tests. Such tests, however,

Fig. 3—Shelton wire fatigue machine.

frequently give misleading results. For this reason it generally is advisable to make the regular long time tests.

For many applications, where repeated stresses occur, it is not necessary to know the endurance limit, which has been defined as the maximum stress to

Fig. 5—S-N or stress cycle diagram.

loads may occur only several times daily, and the estimated number of cycles in the life of the bridge may be 25,000. To use an endurance limit based on 500,000,000 cycles, instead of the fatigue strength for 25,000 cycles, would materially affect the design.

Metals are not perfectly homogeneous, but consist of crystals whose planes of cleavage or slip are oriented in many directions. When sufficient stress is applied, slipping occurs on these planes within the individual grains, which at first may not be sufficient to cause any apparent harm. Under alternating stresses sufficient to produce slip, continued repeated slipping, if of sufficient magnitude, causes minute cracks to start to form and to spread, gradually reducing the area of sound metal remaining in any cross section. One of the unsolved problems in the fatigue of metals is the determination of just when and how any harmless slip under repeated stress changes into harmful slip, causing the formation of a destructive spreading fatigue crack. The end of a crack is a point of highly localized stress, so that there is a strong tendency for a crack to grow. The final fracture occurs with practically no distortion or reduction of cross sectional area, and exposes the natural crystalline structure of the material. This appearance of the fracture originally led to the erroneous conclusion that the metal had "crystallized."^{10, 11} It is now known that the fatigue fractures start in the natural cleavage surfaces of the crystals or along crystal boundaries which give the fractures a crystalline appearance. The crystalline appearance is the result of the fracture rather than the cause.

From this explanation of the mechanism of fatigue, it can be realized that "stress-raisers" should be avoided, meaning internal flaws, reentrant angles, abrupt changes in cross section and other factors which tend to cause local increases in stress not considered in ordinary formulas of mechanics.

No precise correlation exists between the endurance limit and any other physical property. Probably yield strength, tensile strength and ductility all have an effect upon the fatigue properties. Perhaps the closest relationship, at least for some metals, exists between endurance limit and tensile strength. Partly for this reason, the endurance ratio, which is the ratio of these two properties, sometimes is quoted.

The structure of a metal appears to have a definite effect upon its endurance properties. Although relatively pure metals usually have lower endurance limits and lower tensile strengths than alloys, their endurance ratios frequently are higher, apparently because of greater uniformity in structure. The endurance ratio is higher for annealed metal than for cold worked or for quenched material, the greater ductility apparently aiding in relieving any stress concentrations which may be present¹² and possibly because annealed materials contain little if any internal strain. Cold working which increases the tensile strength also increases the fatigue strength, but to a less extent. Apparently there is an optimum degree of cold working above which the fatigue strength is decreased by fracturing of the internal structure.¹ Heat treatment may have different effects upon the endurance ratio. In some cases the retention of alloying elements in solid solution raises the endurance limit and the endurance ratio, and in others the formation of intermetallic compounds may produce serious "stress-raiser" effects, depending upon their form and arrangement. Any internal strain produced during heat treatment may seriously harm the fatigue strength. Strain relieving heat treatment usually improves fatigue strength.

Understressing, which consists of subjecting a material to a safe range of alternating stress before subjecting it to a higher range of stress, tends to increase the fatigue strength of the material. In some cases this increase has been found to be as much as 25%.^{13, 14}

which the material may be subjected an indefinitely large number of times. Instead, it is more important to know the fatigue life at various stresses definitely above the endurance limit. An example of such an application is in bridge construction, where maximum

Occasional overloading of a machine part may actually harm the metal. Such oversteering if repeated enough times will reduce the endurance limit.¹ The application of repeated stresses above the endurance limit does not always lower the endurance limit, however, depending upon the number of cycles of this stress. Some investigators have shown the existence of a damage line, which can be defined as separating, in the S-N diagram, the region containing conditions of stress and number of cycles which cause damage from those conditions in which no damage is done.^{12, 14, 15}

Most of this discussion so far has been concerned with completely reversed stresses. There are, of course, many applications where the stresses are not completely reversed but instead vary from one value to another of different magnitude. Such variations of stress may vary from tension to compression, may be all tension or may be all compression. Tests under conditions other than those of completely reversed stress can not be made in the rotating simple beam type of machine but require machines in which the range of stress can be varied between any limits desired. Many machines of this kind have been devised but no one kind has come into general use.¹⁶

For methods of plotting such data, reference should be made to the reports of the Research Committee on Fatigue of Metals of the A.S.T.M.

The effect of corrosion upon fatigue strength, which usually is very important, is discussed in another article in this Handbook.

Some fatigue tests have been made at low temperatures,^{17, 18, 19} and probably a considerably larger number at elevated temperatures.^{20, 21, 22} In general, these tests indicate that most metals have higher endurance limits at temperatures lower than normal room temperature and lower endurance limits at elevated temperatures.

In general, the tests mentioned in the preceding paragraphs use suitably shaped small specimens, and are intended for the determination of the fatigue properties of a material. During recent years, procedures also have been developed for the fatigue testing of fabricated parts and structures, such as riveted joints,²³ aircraft wing beams,²⁴ and boiler shells.²⁵

Corrosion-Fatigue of Metals

By H. F. Moore*

Corrosion Films on Metals—Under the action of many liquids and gases most metals are corroded. This corrosion takes the form of a film, often only a few molecules thick. This film may give to the metal beneath it a high degree of protection against further corrosion. In that case the film on the metal is usually invisible and it has the power of self healing if cracked. Thicker films, which are characteristic of some metals under the action of a mild corrosive medium, usually do not have this power of self healing, and offer far less protection to the spread of corrosion, especially if the metal is being subjected to repeated stress, causing repeated strain on the film. Even where films do not stop the progress of corrosion they influence the manner in which it proceeds, tending to localize attack at regions under cracks formed under the influence of strain.¹ This localized attack tends to produce pits in the metal, and to render it less able to resist stress on account of the intensification of stress which occurs at any notch or small hole in a piece of metal. The chemical composition of the film depends on that of the metal and on the corroding medium. Oxide films are, perhaps, commonest, but other films, such as phosphate or silicate films are sometimes formed.

Stressless Corrosion and Corrosion Under Steady Stress—If metal is subjected to mild corrosive agents while unstressed, the tendency to form cracks in the oxide film is slight. There is relatively little tendency to form pits, at least in structural steels, and the static strength of the metal is diminished but slightly.² Such corrosion is called "stressless corrosion."

If steel with a thin layer of oxide on it is subjected to a steady load, the thin film of oxide may be cracked at various points, with resulting increased localized corrosion through the cracks. Such intensified corrosion is shown by the "Luders lines" often seen on unpainted structural steel which has been bent or stretched cold,³ causing heavy stress and strain at the bend, and a consequent strain on the film which caused it to crack. However, if the load remains steady, the cracks in the film will tend to heal themselves and the further progress of corrosion will be retarded and perhaps almost entirely stopped.

Damage Under Stressless Corrosion—A metal surface which has been subjected to stressless corrosion, or which is subjected to a combination of steady stress and corrosion, has its resistance to damage under further steady load reduced somewhat, and its resistance to fatigue failure more seriously reduced. However, this damage is far less than the reduction in resistance to repeated stress which is caused by the simultaneous action of repeated stress and corrosion. In any case the damage is due to the "stress raisers"—the microscopic notches formed in the surface of the metal by corrosion. The effect of notches of all kinds in steel has long been recognized as a major factor in causing fatigue fracture of metals, and the magnitude of the effect produced depends upon sharpness of notch, depth of notch, slope of walls of notch, and whether the notch is produced by cutting, by chemical action or by indentation with a blunt tool. Corrosion seems to produce a distinctly destructive type of notch, but stressless corrosion at least under mild corrosive agents does not often produce deep notches.

R. R. Moore's⁴ experiments on S.A.E. 1045 steel corroded without stress by salt spray showed a reduction of fatigue strength (measured by the endurance limit) due to corrosion of 22%. His experiments on duralumin showed a reduction of endurance limit of about 35% after stressless corrosion.

Simultaneous Corrosion and Repeated Stress; Corrosion-Fatigue—If a metal is subjected to a corrosive medium while also being subjected to cycles of repeated stress, the protective film may be repeatedly broken. For steel, corrosion spreads through cracks and forms relatively deep pits which act as stress raisers, and greatly reduce the fatigue strength of the metal. Practically all the known metals of construction are subject to this action under repeated stress which is known as corrosion-fatigue. How rapidly the destructive effect progresses depends upon: (1) the rapidity of formation of cracks in the film compared with the rapidity with which the protective film can be repaired; (2) the relative porosity of rapidly healed and slowly healed films; (3) the influences which tend to produce a wide spread distribution of electrochemical couples over the surface of metal, and hence relatively uni-

*Research Professor of Engineering Materials, University of Illinois, Urbana, Ill.

form corrosion. The corrosion-inhibiting power of colloidal clay in "drilling mud" in oil wells is an example.

The above is a statement of what is now regarded as the principal cause of corrosion-fatigue. There are many phenomena such as the change of electric potentials within the metal due to stress conditions, and the tendency of the products of corrosion to clog up the pits and, perhaps, delay the further spread of corrosion. Usually the prime cause of the damage is corrosion, but the immediate cause of failure is the "stress raiser" effect of the pits.¹

Fatigue Strength of Metals Under Corrosion-Fatigue—The first published account of laboratory experiments on corrosion-fatigue is that of Haigh,¹¹ who made fatigue experiments on brasses while subjected to chemical attack and who later took a prominent part in the study of the effect of sea water in reducing the life of tow ropes for vessels.

In 1925, D. J. McAdam, Jr. began a very extensive experimental study of corrosion-fatigue.¹² His results, and the results of other experimenters have developed the fact that under so mild a corrosive agent as relatively pure water the fatigue limit may be reduced much below that in air. In fact, no definite value for fatigue limit for indefinitely long life under corrosion-fatigue has been found.¹³ In case of corrosion-fatigue limits, it is important to state the limiting number of cycles which were used in the test, and also the frequency of cycles of stress. In noncorrosive fatigue tests the number of cycles of stress is of prime importance, and, within wide limits, the frequency of cycles of stress is of minor importance. In corrosion fatigue tests the time under corrosive action is also of importance. If the frequency of cycles of stress is low, then for a given number of cycles there elapses a relatively long time during which corrosion can get in its destructive work. Hence the endurance limit is lowered. The experiments of McAdam and others showed, with the exception of the stainless steel group, the corrosion-fatigue limit of heat treated alloy steels (based on 10-100 million cycles of stress) is but little if any above the corresponding corrosion-fatigue limit of ordinary low and medium carbon steels. The stainless steel group resists simultaneous corrosive attack and repeated stress distinctly better than do either plain carbon steels or heat treated alloy steels. With nonferrous metals, the effect of corrosion-fatigue is so varied that no general statement can be made.

Values for Corrosion-Fatigue Endurance Limits—Table I is a graphical representation of average value of fatigue limits in air and fatigue limits under a stream of tap water for several groups of metals. Each value is the average of results from a number of reported tests. This table would not be of a high degree of accuracy for predicting the behavior under corrosion-fatigue of any given metal, but does give an idea of the relative effects of corrosion-fatigue for the main classes of structural metals in tap water. A different corroding medium (salt water) might change materially the relative fatigue strength of the metals listed.

The corrosion-fatigue limits for the heat treated alloy steels do not seem to be any higher than those for the ordinary low and medium carbon steels. This is in harmony with the increased sensitivity of high strength steel to notches and other localized "stress raisers."

For a larger number of cycles of stress as given in Table I or for cycles of stress occurring less frequently, the limits would be distinctly less. In his summary Gough¹⁴ makes use of the terms, suggested by McAdam, "total damage" and "net damage." "Total damage" is the percentage reduction from the fatigue limit determined in air to the fatigue limit found when specimens have been subjected to some definite routine of corrosion-fatigue. The "net damage" is the percentage reduction from the fatigue limit of metal subjected to some definite period of "stressless corrosion" to the fatigue limit of specimens which have been subjected to some definite routine of corrosion-fatigue.

From McAdam's data the following tentative relation between stress range and average rate of net damage is given.

$$R = CS^n$$

In which R = rate of net damage in % per day.
 S = stress range in psi.
 C and n are experimental constants.

Gough quotes from McAdam's results values of n varying from 2.6 to 5.7.

Gough¹⁴ notes the report from German investigators that there seems to be some degree of correlation between notch-sensitiveness of a metal and its resistance to corrosion-fatigue.

Table I
Characteristic Results of Corrosion-Fatigue Tests
 Based largely on the work of D. J. McAdam, Jr.

Endurance limits reported are for 20,000,000 cycles of stress. Speed of testing, 1450 cycles per minute. Tests made in rotating cantilever-beam fatigue machines.

Metal	Approximate Composition, %	Tensile Strength, Psi.	Endurance Limit in Air, Psi.	Endurance Limit in Stream of Water,* Psi	Reduction of Endurance Limit by Corrosion-Fatigue, %

*Tested under a stream of fresh water. A fairly representative analysis of the water showed the following composition, values in parts per million: Silica, 11.7; iron and aluminum oxides, none detected; calcium sulphate, 1.89; calcium carbonate, 200; magnesium chloride, 17.3; sodium chloride, 140; sodium sulphate, none detected. This is a rather hard water.

**Increase in endurance limit.

In Gough's⁷ paper the effect of time on corrosion-fatigue is summarized by the conclusion from test results that at low frequencies of stress-cycles the rate of net damage is nearly proportional to the frequency; at high frequencies of stress-cycles the rate of net damage is nearly independent of the frequency.

Few data are available on corrosion-fatigue under cycles of stress other than those involving complete reversal. At the University of Illinois a few corrosion-fatigue tests of structural steel under cycles of flexural stress varying from zero to a maximum gave percentage reductions of the fatigue strength in air of the order of magnitude of the percentages found under cycles of reversed stress.

Gough and Sopwith⁸ have recently reported extensive tests on the influence of range of stress on the resistance of metals to corrosion-fatigue. The corroding

medium used in their tests was a 3% salt spray. They report that for most of the metals tested the effect of variation of ratio of minimum to maximum stress during a cycle (variation from one-direction repeated stress to reversed stress) was about the same under salt spray as was the effect on the fatigue strength in air.

Corrosion-Fatigue in Different Corrosive Media—A general rule cannot be given for the effect of different corrosive media. Perhaps the most nearly general statement possible is that any corrosive medium under which the localization of corrosive attack is determined largely by stress conditions will, if allowed sufficient time, start a spreading fatigue crack. Specimens tested in a free stream of liquid, or in a stream of liquid saturated with air, show greater damage by corrosion-fatigue than do specimens tested in a quiet bath of liquid, especially in a bath free from dissolved air. Distilled water, applied in a stream, causes corrosion-fatigue damage, and for some steels seems as detrimental as ordinary tap water. Acids and alkaline solutions produce various effects. Thum and Holz²⁵ report that strong solutions of soda lyes drastically reduced the fatigue strength of boiler steels, while weak solutions slightly increased the fatigue strength. Some metals which show a good resistance to stressless corrosion show poor resistance to corrosion-fatigue. Again it may be emphasized that the toughness of the protective film on the metal is the main factor in determining resistance to corrosion-fatigue.

Table II
Results of Fatigue Tests in Air and in a Partial Vacuum

Metal	Approx. Composition, %	Condition when Tested	Tensile Strength, Psi.	Endurance Limit Reversed Tension-Compression		
				In Air (A), Psi.	In Vacuum ^a (B), Psi.	Ratio (A) (B)
Armco iron	0.02 Cu, 0.03 Mn	Normalized	49,500	28,900	29,400	0.984
		Annealed	24,000	24,400	0.984

^aPressure in vacuum approximately 0.0008 mm. of mercury.

^bEndurance diagram did not become definitely asymptotic to a stress value. Endurance limit determined for 30 million cycles of stress.

^cTensile strength of lead depends on time under load.

Corrosion in Air—Probably air has a slight corrosion-fatigue effect on most metals although for the steels this effect seems to be quite small. Table II compiled from data by Gough and Sopwith⁸ shows some effects of air corrosion. As compared with the fatigue strength in air the fatigue strength of lead tested in a partial vacuum shows a marked proportional improvement. The stress-cycle diagrams for some aluminum alloys tested in air do not show definite endurance limits even after 500,000,000 cycles of stress, but continue to have a downward slope quite like the stress-cycle diagram of some metals under corrosion-fatigue. In the cases of those metals which do not show a clearly marked endurance limit in air, an investigation of possible corrosion-fatigue in air would be valuable. The tests of Gough and Sopwith show that the main corrosive factor in air is a combination of oxygen and water vapor.

Protection Against Corrosion-Fatigue—Protective Coatings—Since corrosion-fatigue may reduce greatly the fatigue strength of metals the question of protection against this is of major importance. Protection against corrosion-fatigue should be a major factor in the design of structural and machine members. Protective coatings

may offer a greater or less degree of protection against fatigue. A heavy coating of grease has been shown by laboratory experiments¹⁸ to offer a fair degree of protection. A coating of rubber cement²⁰ or a tight fitting rubber sheath²⁴ has been found to give considerable protection. Under salt spray, zinc plating on duralumin afforded an effective degree of protection,⁴ distinctly better than a coat of pure aluminum sprayed on. With the same metal, coatings of organic resins and enamels gave a good degree of protection especially if the material had been anodized.

Naturally noncorrosive metallic coatings suggest themselves as protectives of corrosion-fatigue. Fuller² found that chromium plating was quite effective on steel exposed to steam. Harvey¹² has made a rather extensive study of zinc as a protective coating against corrosion of steel. He studied hot galvanizing, sherardizing, and electroplating as means of applying the zinc coating. His results show that for uncoated specimens of a steel with about 100,000 psi. tensile strength, the reduction of endurance limit (10,000,000 cycles of stress) of a steel with an in-air endurance limit of 60,500 psi. was 66% under a stream of tap water. For galvanized and sherardized specimens the reduction was about 33%. For electroplated specimens there was no reduction. It seems well to note that the electroplated specimens were not pickled but were merely degreased by alcohol and ether. Harvey holds that all the coatings prevented the contact of water with steel. Microscopic analysis showed that for the galvanized and sherardized steel there existed a layer of intermetallic compounds of alloys some of which were probably very brittle, and Harvey suggests that cracks starting in this brittle region and spreading into the steel were the cause of lower fatigue strength. Gerard and Sutton⁴ also found that electroplating with zinc was effective in reducing corrosion-fatigue damage to duralumin. Nitriding steel has been used to give it a definite resistance to corrosion-fatigue. In some specimens of nitrided steel under corrosion,¹⁵ fatigue failure started in the core of the specimen and afterward the nitrided case peeled off.

Recent tests have been reported by Sopwith and Gough.²² They state that the essential requirements for protective coatings against corrosion-fatigue are: (1) The coating must adhere firmly to the base metal. (2) Either it must be anodic to the steel base or it must be continuous and nonporous. In practice it is difficult to secure and maintain continuous, nonporous coatings, hence it is preferable that the coating should be anodic to the steel base. Then it will afford some protection even when its continuity is broken. (3) Its mechanical properties must not be such as to reduce fatigue resistance in air. If it is not sufficiently adherent to be able to transmit cracks to the steel, the coating itself must not crack at too low a stress and thus render the protection purely anodic at an early stage.

Sopwith and Gough found that under a 3% salt spray a satisfactory degree of protection was afforded by galvanizing, sherardizing, and sprayed aluminum plus enamel. A fair degree of protection was afforded by zinc plating, cadmium plating, and sprayed aluminum. A phosphate coating plus enamel and an enamel coat alone gave some protection but were not nearly so effective as the metallic coatings. Enamel was found to improve the protection given by sprayed aluminum, but both enamel and oil reduced the protection given by cadmium plating.

Protection Against Corrosion Fatigue by Rolling the Surface—Tests in Germany²⁸ showed that resistance of certain steels to corrosion-fatigue was somewhat increased by cold working the surface. The cold working seemed to "smooth out" the minute projections and notches in the surface and to offer less area for corrosive attack. Matthew¹⁹ indicated that simultaneous corrosion and abrasion of steel showed a tendency to a mutual inhibition of destructive effects. This was explained by the reduction of the grinding action of abrasion which became a polishing action under the lubricating effect of the corrosive liquid.

Chemical Inhibitors of Corrosion-Fatigue—In some cases, for example, oil well pipes and sucker rods, it is possible to add chemicals to the corroding medium which will partly or wholly inhibit its damaging action. Dilute solutions of trisodium phosphate¹⁴, ²⁸ and sodium carbonate¹⁰ have been found to have some retarding effect on corrosion-fatigue damage in steel. Tests showing effective chemical inhibition of corrosion-fatigue damage have been made by Speller, McCorkle, and Mumma.²⁴ They used sodium dichromate (a strong oxidizing agent) in the water sprayed on the specimens, and found that it was an almost perfect "inhibitor" of damage due to corrosion-fatigue. This is probably due to the fact that the strong oxidizing action of the sodium dichromate built up protective film so rapidly that cracks were not formed, or at least never penetrated to the surface of the metal under the protective film. This research also emphasized the importance of small local dif-

ferences of surface condition, the effect of which may be far more destructive than the effect of the general environment.

Corrosion-Fatigue of Welds—Welds in structural steel do not seem to show any great difference in resistance to corrosion from that of the parent metal. Corrosion fatigue results¹² have been determined for stainless steel and for resistance and gas welds. The gas weld was anodic to the base metal while the resistance weld was cathodic. Heat treatment which dissolved carbides increased the resistance to corrosion-fatigue. In general, there seems no evidence that welded joints are more susceptible to damage by corrosion-fatigue than is the base metal welded.

Cumulative Effect of "Stress Raiser" and Corrosion-Fatigue—Dolan¹ has carried out tests under reversed torsion on standard fatigue specimens, specimens with sharp fillets and specimens with holes. Tests were made in air and under a stream of tap water. Low carbon steel and heat treated S.A.E. 3140 steel were tested. The damaging effect of combined corrosion-fatigue and a stress raiser were decidedly greater than the effect of either alone for the S.A.E. 3140 steel, especially for the specimens with holes. For the low carbon steel the damaging effect of combined corrosion-fatigue and a stress raiser was but slightly larger than that for corrosion alone. Later tests of heat treated S.A.E. 3140 steel and several low alloy steels under reversed flexure yielded similar results.

Corrosion-Fatigue and Caustic Embrittlement—In connection with steel pressure vessels an interesting phenomenon is that known as "caustic embrittlement." Under steady, high stresses and in the presence of a strong alkaline solution intercrystalline cracks have developed both in vessels in service and in specimens under laboratory tests. It seems probable that the chemical action which starts these cracks is due to the presence of small quantities of impurities in the solutions used, and silicates seem to be indicated as impurities. The phenomena of corrosion-fatigue seem to be distinctly different from those of caustic embrittlement. The corrosion-fatigue cracks when started in steels and most of the nonferrous metals spread within the crystals just as fatigue cracks spread when tested in air. Unpublished results by Betty at the University of Illinois show that under the corrosive influence of water which had been chemically treated so as to prevent caustic embrittlement, corrosion-fatigue took place in boiler steel.

Corrosion-Fatigue Failures in Service—Corrosion-fatigue failures have occurred in marine propeller shafts, ship's rudder main piece; steering hubs and stub axles of automobiles; boiler and superheater tubes; turbine rotors, discs, and blading; street car and locomotive springs; piping conveying corrosive liquids; wire of airplane frames; pump shafts; pump rods; pump bodies; watercooled piston rods of Diesel engines; and steel railway sleepers. Gough¹ feels that the occurrence of corrosion-fatigue in marine boiler plates has not yet been definitely proven, differing in this opinion from McAdam. In the service failures studied the exposed surfaces have in some cases suffered appreciable damage by general corrosion, but the reduction of dimensions by corrosion is quite insufficient to explain the great reduction of strength. Corrosion-fatigue depends on localized action.

Simple Statistical Methods as a Guide in Control of Operations and of Quality of Product*

In any single manufacturing operation whatever there is bound to be some lack of complete uniformity which may affect the usefulness of the product. In a sequence of operations the likelihood of significant variation of the final product is much greater, as the maximum deviation from the mean in the final product is usually the sum of the maximum deviations from the mean in each step in the sequence of operations. Thus it is inevitable that there will be some variation between the units of any metal product no matter how carefully each of the many steps in its manufacture has been carried out; and, in general, such difficulties as there are arise from those units which differ most widely from the average quality as specified. For, to the user, extra good units do not make up for poor units; what he wants, especially in these days of automatic operations, is a product no unit of which falls outside certain limits, and the limits which he is willing to tolerate are becoming always closer. We are therefore forced to consider the extent and frequency of departure from the average, or the mode of distribution of the several cases about the average; and this implies that if we are to treat these matters intelligently we must have recourse to statistical methods.

Conclusions deduced from statistics have not always commanded universal assent, but experience with the application of statistical methods to metallurgical and manufacturing operations which are reasonably well controlled, has demonstrated their usefulness and reliability, when properly used and interpreted. By their use it is possible to differentiate variation which is inherent in a given process from variation due to some abnormality in that process. Methods are available which enable us to decide, from the variation in test results of selected samples, in how far the quality of the individual units is being maintained within the requisite limits, or to foretell the probability of performance even where only limited data are available. They also serve to bring out relationships between actual variables in a process even where there is no functional relationship between these variables. They suggest moreover that in some specifications, rigid limits—for instance, of composition or of quality—could, with advantage to all concerned, be replaced by the requirement that a stated high percentage of the material should be within the stated limits.

The statistical methods most frequently employed involve the use of frequency distributions, cumulative distributions, control charts, correlations, and significance tests. It is manifestly impossible, in the space available, to discuss all of these methods in such a way that a reader, previously unacquainted with them, could apply them; and their seeming complexity might indeed discourage him from trying them. We are therefore limiting ourselves to an outline of a simple case—the construction and use of frequency curves—which involves little mathematics; and in the appended references we refer the reader who becomes interested in going further, to a number of pamphlets and books which set forth more mathematical methods of statistical analysis and discuss the whole subject broadly. It may be added that most of these methods are less difficult than they may seem at first sight; when once set up they may be used and applied by a person without special aptitude for mathematics, provided always that one uses common sense in arranging the observations and in interpreting the results.

The frequency curve represents the frequency of occurrence of the several values, or mode of distribution of the value, of a single variable X for a large group of units or batches of the product. Its useful interpretation is based on the presumption that the group is large enough to permit us to consider the variation of X as being unaffected by the variation of whatever other factors may influence the quality or fitness of the product for its intended use. The merit of frequency curves is that they enable us to analyze, factor by factor, complex situations in which a large number of possible variable factors are concerned, without bringing in any personal bias; this enters only when we begin to seek the causes to which the variation in product is to be attributed.

*This was written by John Johnston, with the aid and advice of J. E. Gould, National Tube Co., Lorain Works, Anson Hayes, American Rolling Mill Co., and W. A. Shewhart, Bell Telephone Laboratories. It is presented as a simple introduction to the subject, designed to arouse interest on the part of those still unacquainted with this valuable tool.

To illustrate the method of drawing and using a frequency curve, it is best to consider a specific example. For this we shall take a large group of heats of steel, considering as the variable X the casting temperature, which ranged from about 2700 to 2950°F. The difference is the total range required on the horizontal axis. This range we divide into equal intervals, or unit cells, each representing in this case an interval of 20°. This interval was chosen because the accuracy of measurement is of this order, and there is no point in making the interval smaller than the probable accuracy of the data under consideration. The choice of size of unit cell does not affect the curve materially if the number of cases (heats) is large enough and if the number of intervals is not too small; it is a matter of judgment, governed largely by the degree of accuracy of the data and the size of the group of cases available. If the interval is too small, there will be, with a limited number in the group, too small a number in each and the curve will be irregular and show details which may well be without significance; if the interval is too wide, the significant details may be masked. In general it is preferable to have a dozen cells if the accuracy of the data and the variation of X make this possible. Having decided on the size of the interval, we examine the records for the group, and count the number of cases in which X falls within each of the several intervals or cells. When the whole group has been counted in this way, the number in each group is reduced to a percentage of the whole, and this percentage is plotted as ordinate at the center of each cell on the horizontal scale. These points are connected by straight lines as in Fig. 1; or vertical blocks or bars may be used to show the relative number within each interval of the variable. The resulting frequency distribution is usually not quite smooth, but is smoother the larger the group; consequently little significance is to be attached to small irregularities, particularly when the group is small.

It is to be noted

that each frequency distribution deals with a single variable only, the other co-ordinate being merely a number. Consequently there is a separate curve for each variable considered, without reference to the other possible variable factors. We may, however, use as the variable the sum or product or quotient of two recorded variables, as derived separately for each case in the group; but a combination of variables should

Fig. 1—Typical frequency curve; casting temperature of a large group of heats before, and after, a change in practice.

in general be tried only if there is a specific reason for doing so. A single diagram should be concerned with only one variable, but it is highly desirable to draw on the same sheet the corresponding diagram for groups to be compared. Such a comparison may be made on similar groups of heats made at different periods (for instance, before and after some change in practice) or in different mills, or of "good" with "bad" heats as separated by any criterion of quality that may be available (for instance, hardness or ductility). Such a comparison is illustrated in Fig. 1. We may also arrange a large group in order of increasing Y , where Y is a second variable (that is, manganese or sulphur content), divide into three (or four) equal subgroups, and then compare the frequency distribution of the variable X for the highest and for the lowest of these subgroups; this shows at once how far the distribution of the values of X is affected by the factor Y .

The frequency curve for the variable X shows at a glance, for the group of cases included in the diagram: (1) the total range of X ; (2) the total number of cases falling within, or without, any specified limits of X ; (3) the most frequent

value of X ; (4) the general symmetry of the distribution of the values of X about the peak. Obviously a high narrow curve corresponds to a close control of the factor X ; a low broad curve indicates inadequate control. Yet the average value of X may readily be the same for both of the distributions just named, or indeed for any number of different modes of distribution; this shows that averages have little significance unless the shape of the distribution of the values averaged is substantially identical in all the groups compared. Thus in comparing similar groups of product made at different periods or in different ways or in different places, we may have the same average value of X yet with better or worse control of its variation as indicated by a narrower or broader loop respectively.

In general, the outstanding advantage of a frequency curve is that it depicts characteristics of the distribution of the values of one variable at a time for a group of cases, and that it is based on no assumptions other than that the number in the group is large enough to insure that the distribution of all other variable factors is accidental and so without specific directive effect upon the single variable considered. This implies that the data have been grouped rationally, based upon a fundamental knowledge of the process in question; in other words, that the group considered does not comprise two (or more) subgroups which are known to differ specifically from one another with respect to some factor. The method is applicable to any factor which can be obtained repeatedly as a numerical quantity; from residual carbon to temperature at any step in the process of manufacture, from cost or overall recovery of product to tensile strength of similar samples or diameter of similar wires. It furnishes what may be called a statistical aspect of quality with respect to any given step of a process or any given property of a product; but being by definition statistical does not of itself indicate the why or wherefore of any differences it may reveal. Nevertheless, if on comparison of two similar groups, one of "good," the other of "bad" product, we find the two frequency curves for any given variable to be substantially identical, we can conclude with some confidence that this particular variable is substantially without influence upon the "goodness" of the product as indicated by the criterion which was used; moreover if the pairs of curves for each of the variables observed are substantially identical, we should look for some other factor which might influence the "goodness" or "badness" of the product, or inquire into the significance of the criterion used to distinguish "good" from "bad."

If the variation of X is believed to be random, then the cumulative curve, derived from a comparatively large group, may advantageously be used to forecast the per cent of occurrences which will fall within any specified limits. The following table illustrates how such a curve may be readily prepared:

Interval of " X "	% of All Observations	Cumulative % of Observations
52-54	1.0	1.0
55-57	2.5	3.5
58-60	4.0	7.5
61-63	12.0	19.5
64-66	16.0	35.5
67-69	19.5	55.0
70-72	19.0	74.0
73-75	15.0	89.0
76-78	8.0	97.0
79-81	2.0	99.0
82-84	1.0	100.0
Total	100.0	

Such a cumulative curve may be plotted satisfactorily on arithmetic probability graph paper.

One of the recent developments in statistical technique of particular usefulness in detecting assignable or findable causes of variability in the properties of metals during production is the statistical quality control chart. A recent paper by Chancellor briefly illustrates some of the uses of this technique in the steel plant. By means of an analysis of a series of comparatively small samples taken in the order of the production of the material, it is often possible to detect the presence of

causes of variability which should, from an economic viewpoint, be removed from the process. As an example, Fig. 2 shows a control chart for chipping time taken from this paper, in which the average for successive small groups of samples is plotted. When this average falls outside the appropriate limits, it is usually possible to find and remove the cause, thus reducing the variability. Two such kinds of causes were found in this case, as is indicated in the figure. The use of such techniques leads to many economies, examples of which will be found in the literature cited below.

It would lead too far to give a complete discussion of the application of these methods; for this the reader is referred to the books and pamphlets noted below which treat and illustrate the several methods in the requisite detail.

Fig. 2—Control chart for chipping time (in man-hours per unit of surface area) of groups of heats in chronological order.

Spectrographic Analysis

By Charles C. Nitchie*

Introduction—The fundamental basis of spectrographic analysis is the fact that every element, when converted by heat or electric discharges into the form of a luminous gas or vapor, emits light which is definitely characteristic of that element. A simple illustration of this phenomenon is the flame test, frequently used by the chemist for the qualitative indication of the alkali and alkaline earth metals. He introduces a fragment of material into the colorless flame of a Bunsen burner. If the flame is colored a bright yellow, he concludes that the element sodium is present. A violet color indicates potassium; a deep red, lithium; or a yellow-green, barium.

A test of this kind, however, can be used to only a limited extent. Relatively few of the elements emit their characteristic radiations at the temperature of the Bunsen flame. Few of them yield light so nearly monochromatic that a visual observation of the color of the flame can provide a safe basis for identification. Moreover the eye sees only an integrated average when more than one color is present and cannot separate a complex color into its components. Consequently, visual observation would be totally inadequate for the analysis of mixtures of two or more elements. For these reasons color is usually disregarded in work of this kind, radiations are designated by wave lengths and recourse is had to instrumental methods of observation which permit the clean cut separation and accurate measurement of the wave lengths emitted by the elements under consideration. The instruments used are the spectroscope and spectrograph, the former for visual observation, the latter photographic.

The Spectroscope—The spectroscope is of more limited value than the spectrograph for metallurgical analysis. Its use is confined to the comparatively narrow band of radiations which the eye can see whereas many of the elements emit their strongest and most characteristic radiations in the ultra-violet or infra-red which are invisible. Furthermore, with the spectroscope, specific search must be made for the lines of each individual element, in order that its presence or absence may be established. This search must be made while the sample is in the luminous vapor condition, with the probability that some will be missed because they have been completely expelled from the sample during the time when others were being observed.

The Spectrograph—The spectrograph is free from the limitations of the spectroscope. The photographic plate records not only the visible but also the ultra-violet and when suitably sensitized, a considerable portion of the infra-red. It records all radiations simultaneously and provides a permanent record from which the essential facts may be read at any time, even though the sample is no longer available. Its response to radiation is cumulative so that, with sufficiently long exposures, readable impressions can be obtained from radiations too weak to be observed visually. For these reasons the spectrograph is much to be preferred for analytical work and is the instrument that will be discussed here.

Spectrographs are of two major types, one using a prism, the other a diffraction grating to disperse the spectrum. The diffraction grating has the advantage that it produces a spectrum that is nearly "normal," that is, one with the same dispersion at all wave lengths, so that two lines, differing from each other in wave length by a given amount, are separated by the same distance on the photographic plate, regardless of wave length. With the prism, dispersion is much greater at short wave lengths than at long, with the result that the spectrum is more crowded in the long wave region and wave lengths cannot be measured as accurately there as in the short wave length range. This advantage is largely offset by a number of limitations, the most serious one being the fact that good gratings are difficult to obtain, their manufacture being attended by so many difficulties and uncertainties that no commercial manufacturer has found it possible to undertake their production. Less serious objections are the presence of "ghost lines" in the spectrum, due to slight irregularities in the rulings and the overlapping of successive orders of spectra, which sometimes introduce uncertainties in interpreta-

This article not revised for this edition.

tion. For these reasons, grating spectrographs are not extensively used for spectrochemical analysis and are not considered in the following discussion.

In its simplest form (Fig. 1) the prism spectrograph may be thought of as a photographic camera, adjusted and focused to take pictures of a narrow slit through which comes the light to be examined. Between the lenses which form the image of the slit on the photographic plate is placed a prism which by refraction, bends the light, the amount of bending being determined by the material

Fig. 1—Simple spectrograph.

of which the prism is made, the angle between its faces and by the wave length of the light. Light of short wave length is bent more than that of long wave length. If, now, the slit is illuminated with red light of a single definite wave length, the light will be bent to only a slight degree on passing through the prism, and the picture of the slit will be formed by the lenses toward the right-hand end of the photographic plate. If the slit is illuminated with light of shorter wave length, say violet, the bending will be more and the slit image will be formed

Fig. 2—Optical system of Littrow type spectrograph.

farther to the left. Ultra-violet radiation is of still shorter wave length and consequently undergoes still more deviation, the slit images of the shortest wave lengths being formed at the left end of the plate.

If the light entering the slit is made up of more than one wave length, each will form a separate picture of the slit and these pictures or "spectrum lines" will be distributed along the plate in positions corresponding to the wave lengths of the radiations producing them. There will thus be no difficulty in detecting with certainty any one wave length in the presence of others, provided the entrance

slit is made sufficiently narrow to avoid overlapping of images, when the radiations to be distinguished differ but slightly in wave length. The wave length corresponding to any line can be determined by measuring its position in the spectrum with reference to lines of known wave length. Since the radiation emitted by each element is made up of certain definite discrete wave lengths which are always the same regardless of what other elements are present in the substance under investigation, and since these wave lengths are accurately known and are available in published tables, it is possible to identify each line in the spectrum from its wave length and thus to gain a complete knowledge of the composition of the substance.

Some elements like the alkali metals yield spectra that are relatively simple, containing but a few lines. Others like iron, nickel, and tungsten yield highly complex spectra, with thousands of individual lines. This must be kept in mind when selecting a spectrograph, for a particular purpose.

These instruments are made in a number of sizes and types, with corresponding differences in dispersion and resolving power.

The dispersion of a prism is the separation it will give between different wave lengths. Strictly it is the difference in the angles at which two rays, differing in wave length by one unit,* emerge from the prism.

It is usually more convenient with a spectrograph to consider what is termed the linear dispersion, the number of Å corresponding to a separation of 1 mm. on the photographic plate. This takes into consideration not only the angular dispersion, but also the focal length of the lens which focuses the lines on the plate, since the greater the distance at which the lines are focused, the greater will be the separation of two lines with a given angular separation.

Resolving power is a measure of the ability of the prism to separate two lines differing but slightly in wave length. It bears the same relation to dispersion in a spectrograph as that between resolving power and magnification in a microscope. Just as no amount of magnification can reveal details of structure with a microscope, when using an objective of too low resolving power (determined by its numerical aperture) so, in a spectrograph, no increase in the linear dispersion will serve to separate close pairs of lines unless the prism used has the necessary resolving power, which is determined, for prisms of a given refractive index and angle, by the size of the prism. All prisms having the same refractive index and angle between refracting surfaces have the same dispersion regardless of size, but their resolving powers will vary in direct proportion with their sizes provided the beam of light which passes through the prism is broad enough to fill the entire length of the refracting surfaces with light. This, of course, means that the collimating and camera lenses must also be of proportional sizes.

It is thus obvious that to obtain satisfactory results in the analysis of materials that yield complex spectra, in which the lines are numerous with but small differences in wave length, it is necessary to use a spectrograph with a large prism and lenses to give the required resolving power and with lenses of long focal length to make that resolving power effective.

*Wave lengths are usually expressed in Angstrom units (symbol, Å). The symbol I.Å. (International Angstrom) is sometimes used to indicate that the unit used is based on the present International Standard, which by agreement assigns to the red line of cadmium the wave length 6438.4696 I.Å., a value determined by means of the interferometer in comparison with the international standard meter.

$$1 \text{ Å} = 0.1 \text{ m}\mu = 10^{-7} \text{ mm.}$$

The visual spectrum includes wave lengths from about 4000-7500 Å. Those shorter than 4000 Å comprise the ultra-violet and those longer than 7500 Å the infra-red regions.

Fig. 3—Index for the identification of aluminum lines.

Size of Spectrograph—There are, of course, many materials the spectra of which do not require the use of large spectrographs. Most of the common nonferrous metals have comparatively open spectra with little danger of confusion. For such, a spectrograph of moderate dispersion and resolving power will usually be sufficient, although even then difficulties may arise if constituents are present which give lines close to those of others. It is a wise precaution, therefore, when investing in instruments of this kind, to make sure that the one selected is adequate to give unquestionable results on all analytical problems that are likely to arise.

Spectrographs of small and moderate sizes are usually arranged in the manner indicated in Fig. 1, the light entering the slit at one end and passing through the collimating lens, prism, and camera lens to the photographic plate at the other end. With large instruments, however, this arrangement is not so convenient as that known as the autocollimating, or Littrow type (Fig. 2).

The slit is placed at the same end as the photographic plate. But one lens is necessary and the prism has a metallic reflecting coating applied to its back surface. Light entering the slit is directed to the lens which renders the rays parallel and passes them on to the prism where they are refracted and strike the reflecting surface normally. They are reflected back along their incident path, are further refracted on emerging from the prism, and again pass through the lens which focuses the spectrum on the photographic plate. Several advantages result from this arrangement. The total length of the instrument is but half that of one of the conventional type and of the same focal length. The "around-the-corner" structure is avoided, permitting a straight line construction which occupies less space in the laboratory, is easier to handle when the instrument has to be moved or shipped, and makes possible a more convenient arrangement for operation. The light source and photographic plate holder can be brought near together, so that all manipulation is brought within reach of the operator at one position. Furthermore, it requires but a single lens and a prism of but half the thickness of that required by the other type, a consideration which is particularly important in the case of quartz optical parts because of the scarcity and high cost of quartz of large size and good optical quality.

If the instrument is to be used only for the recording of the longer wave lengths of the spectrum, glass optical parts may be used throughout the system. If, however, the ultra-violet is also to be observed, glass will not serve as it is opaque to wave lengths shorter than about 3600 Å. Since most of the metals have their strongest lines in the region of shorter wave lengths, a spectrograph to be used for general metallurgical analysis must be provided with optical parts that will transmit these wave lengths. Quartz is usually employed, as it has the requisite short wave transmission and is found in natural crystals large enough for the manufacture of prisms and lenses of the necessary size.

The Light Source—Various devices are used for exciting the radiations. They include: (1) The Bunsen burner; (2) the oxy-acetylene flame; (3) the electric arc; (4) the high tension spark; (5) the vacuum discharge tube; (6) the electric furnace; and (7) the explosion of fine wires by heavy condenser discharges.

The Bunsen Flame—The Bunsen flame, with its relatively low temperature, will excite the radiations of the alkali and alkaline earth metals and a few others, but is not effective with most of the elements that are encountered in metallurgical work. Consequently it is rarely used.

The oxy-acetylene flame is much hotter than the Bunsen flame and will excite radiation from many more elements. It has been used by Lundegardh¹ and others with considerable success on a variety of materials. The sample is used in the form of a solution which is introduced into the gas stream as a fine spray, with the aid of a special form of atomizer.

The electric arc is the light source most generally used. The sample may take any form that may be convenient. Rods or reasonably heavy strips of metallic samples may be used as electrodes and the arc struck between them, with sufficient resistance in series to give the required current, usually 5-15 amperes. This is the most satisfactory form when the metals are of sufficiently high melting point to withstand the high temperature of the arc without melting down. Since the metals usually have high heat conductivity it is often possible to use metals of relatively low melting point in this way if the electrodes are of large cross section

so that the heat is carried off rapidly from the points where the arc is struck, and only the tips reach the fusion temperature. The main advantage of the use of "self-electrodes" is the fact that the light emitted comes entirely from the sample and there is no chance for confusion with extraneous lines in the spectrum which are always present when supporting electrodes of other materials are used.

Sometimes it is impossible to obtain the samples in forms that can be used directly as electrodes. Small fragments, drill chips, hack saw dust, powders, and solutions are usually introduced into a cavity drilled in the tip of a pure carbon rod which is mounted as the lower electrode of the arc, a second rod of the same pure carbon serving as the upper electrode. Artificial graphite is the form of carbon most commonly used. Special grades are available commercially from which metallic impurities have been removed either by repeated heating at the temperature of the graphitizing furnace, or by chemical treatment followed by such heating. The grade which is most widely used may contain minute amounts of boron, calcium, copper, magnesium, silicon, titanium, and vanadium, the lines of which will appear in the spectrum. They may be allowed for, to a large extent, by photographing the spectrum of the blank electrodes alongside that of the sample and ignoring lines common to both, if no stronger in the sample spectrum than in the blank. This procedure is subject to some uncertainty as the impurities may not be evenly distributed throughout the graphite. Furthermore the intensities of electrode impurity lines are considerably affected by the other elements present in the samples, some elements having the effect of enhancing, others of suppressing the lines of other elements. For these reasons it is not possible to make exact allowance for electrode impurities from the blank electrode spectrum. In critical cases, when the analyst must be certain of the presence or absence of minute traces of the elements that do occur as impurities in the ordinary grade of spectroscopic graphite, it is necessary to use more highly purified graphite from which these impurities have been more completely eliminated. A method for purifying electrodes is described by Standen and Kovach.²

One source of occasional difficulty with the carbon arc is the presence in its spectrum of numerous broad and intense bands due, not only to carbon but also to molecules of its oxides and nitrides (cyanogen) formed when the arc burns in air. They are often so strong as to hide completely the lines of other elements present in the sample and having wave lengths lying within the bands. It is a fortunate circumstance that comparatively few of the metals have their most important lines in the regions so affected, and most of these also have lines of good intensity at wave lengths where they will not be subject to this type of interference. For the few cases in which it is necessary to observe weak lines in the regions covered by the carbon bands it is sometimes necessary to use supporting electrodes of other materials than carbon. Copper or silver electrodes are sometimes employed. They are not so effective as carbon in bringing out extremely small traces because they do not reach so high a temperature and consequently do not vaporize the samples as readily as does the carbon arc.

Direct current is necessary for the maintenance of an arc between metallic electrodes or those of graphite. Alternating current will not serve. The arc can be operated from a 110 volt d.c. line with care and close attention, but greater steadiness and freedom from interruptions are insured by using a higher line voltage, 220-250 volts. A rheostat is connected in series with the arc to regulate the current. This will vary with the nature of the samples and the purpose of the analysis. No definite rules can be set down as the most favorable conditions must be determined by experiment for each problem as it arises. Highly volatile samples usually require lower amperage than those of a more refractory nature in order to avoid too rapid volatilization. Some materials, such as some of the alloy steels, throw off a shower of sparks, consisting of particles of white hot metal, which may embed themselves in the surface of the condensing lens if too high current is used. On the other hand, too low a current will often fail to produce the necessary electrode temperature to volatilize a highly refractory sample and will thus unduly prolong the exposure.

The amount of sample to be used will depend on many conditions, including the nature of the material, the form in which it is received, the elements to be detected or determined and the concentrations in which they are present. A fraction of a milligram will often suffice for an indication of the major constituents.

Fifty milligrams will usually permit a complete analysis for both major constituents and impurities present in minute traces.

Arc excitation yields a spectrum which permits the detection of all the metallic elements, but only a few of the nonmetals. Hydrogen, oxygen, nitrogen, the halogens, and the rare gases do not emit their spectra in the arc. Phosphorus and selenium do so at relatively high concentrations, but are not nearly so sensitive as most of the metals in the range of wave lengths readily available with ordinary spectrographs and photographic emulsions. Their strongest spectrum lines fall so far out in the ultra-violet as to require, for the detection of small amounts, the use of a vacuum spectrograph and specially sensitized plates. The same is true of sulphur which, however, also yields lines of considerable intensity in the near infra-red. With the recent development of infra-red sensitive plates there is reason to believe that sulphur can be detected in amounts comparable with many of the metals. Carbon yields a few strong lines and, when the arc is burned in air, numerous complex bands due to oxide and nitride molecules. Attempts have been made to develop methods that would permit the spectrographic detection and estimation of carbon in iron and steel but without much success, and there is at present little prospect that the spectrograph will provide a substitute for chemical methods for carbon analysis.

The high tension spark is extensively used in much the same way as the arc, samples and electrodes being of a similar character. The electric discharge, however, is quite different. In the first place, it is at much higher potential, commonly from 5000-20,000 volts. Secondly, it is usually an alternating current discharge drawn from an induction coil or, more commonly from a step up transformer operated from the ordinary 110 volt, 60 cycle supply. The amperage is much less than with the arc and the electrodes do not reach the high temperature of arc electrodes. Consequently the amount of vapor raised to incandescence is far less than in the arc. The spark is usually less sensitive in the detection of extremely small amounts of minor constituents and impurities, and longer exposures are required to obtain comparable line densities on the photographic plates.

The intensity of the spark is greatly enhanced by inserting a condenser in the high tension circuit, usually in parallel with the spark. This may be a Leyden jar or a plate condenser with glass, mica, or oil dielectric.

The spectrum of the spark will include not only lines of the sample and electrodes but also numerous air lines emitted by the atmospheric gases. The air lines can be largely eliminated by inserting a self-induction coil of a few microhenries in series with the spark.

Because of the high potential in the spark, the spectra produced by it often differ in important respects from those produced by the arc. Certain lines will be brought out strongly in the spark spectrum that are weak in or completely absent from the arc spectrum. Some lines that are prominent in the arc spectrum will be suppressed in the spark. These differences are due to the fact that most of the radiations in the arc arise from neutral atoms, those which still retain their full complement of electrons, whereas in the spark many of the atoms have lost one or more electrons—in other words are ionized—and consequently behave like distinctly different elements. For this reason care must be exercised to avoid confusion when comparing arc with spark spectra of any material. Some "spark lines" will usually appear in the spectrum emitted by the arc and some "arc lines" in that emitted by the spark, but their relative intensities will differ with the prevailing electrical conditions and also with the particular combination of elements in a given sample.

The spark has some advantages over the arc that recommend it for certain purposes. It will usually maintain its position with greater constancy, having less tendency to wander from place to place on the electrodes thus requiring less attention on the part of the analyst to keep it properly lined up with the spectrograph. For this reason, too, it can be used more readily for the examination of restricted areas in a sample. Small spots, where segregation is suspected can be examined by directing a spark to the suspected spot, with less danger of interference from the surrounding material than would be experienced with the arc. Because of the lower electrode temperature it is possible with the spark to obtain the spectrum of a specimen without altering its form or removing any appreciable amount of material. This is sometimes desirable in the analysis of rare specimens, items of

evidence in criminal cases or other objects, the original form of which must not be changed.

The principal disadvantages of the spark are its lower degree of sensitiveness in detecting extremely small traces and the highly objectionable noise produced by the condensed spark.

The *vacuum discharge tube* is used in obtaining the spectra of gases. The familiar neon sign is an example of such a tube in which an electric discharge at fairly high potential is passed through the gas at relatively low pressure, the light being observed either through the wall of the tube or through a suitable window applied over the end. Such devices are of little application in work with metals, although there is a possibility that methods could be developed for nitrogen in which these tubes could be used.

The *electric furnace*, as a means for exciting the spectrum, is used in the study of the emission from metallic vapors at different temperatures. It has provided important data for those who are concerned with the origin of spectra and the energy relations involved in the emission of different spectral lines, but has not been used for spectrochemical analysis.

The *wire explosion method* involves the explosion of a fine wire of the metal to be analyzed by passing through it an instantaneous current of high amperage from a condenser of large capacity charged to a high potential. In this way enormously high temperatures are obtained and light of great intensity is emitted. The method has been successfully applied to the analysis of the fine tungsten wires used as filaments in incandescent lamps and vacuum tubes. It has also been used for the analysis of other materials by coating the wire before explosion with a film of the sample material. This method has not come into general use but appears to have promising possibilities for some types of work.

Illumination System—The way in which the light from the source is introduced into the slit of the spectrograph has a great deal to do with the quality of the lines as photographed on the plate. A detailed discussion of the many factors involved is beyond the scope of the present article. An excellent demonstration, with experimental data has been presented by Stockbarger and Burns.³ No one method will provide the best illumination for all purposes.

The sharpest lines will be obtained when a small source is placed at a considerable distance from the slit, with no condensing lens between. This, however, utilizes but a small part of the emitted light and necessitates undesirably long exposures.

Another method is to place a diffusing screen, such as a ground quartz plate between the light source and the slit, illuminating by diffused light. This insures more even illumination of the whole length of the slit than the method using a condensing lens, but has the disadvantage, when used with the carbon arc, that it introduces into the spectrograph not only the light from the arc proper, but also a flood of white light from the hot electrode tips, producing a strong background of continuous spectrum.

By far the most common method of illumination is to focus a magnified image of the source on the slit by means of a condensing lens. While this does not produce so sharp lines as those obtained with the first method, they are sufficiently sharp for most practical purposes and the method has several distinct advantages. More light is introduced into the spectrograph, resulting in shorter exposures. White light can be excluded by using sufficient magnification to throw the images of the electrode tips above and below the open length of the slit, thus limiting the light entering the spectrograph to that from the arc or spark. Furthermore, once the condensing lens has been properly located, it provides an accurate indicator for locating the light source in the optical axis of the spectrograph. All that is necessary is to bring the source into such a position that its image falls on the slit.

An optical bench, rigidly attached to the spectrograph, with supports for light source and condensing lens, is the best means for securing correct alignment and maintaining it.

Sometimes it is desirable to have means for reducing light intensity, in order to avoid overexposure of the photographic plate, when the exposure time must be extended to permit complete volatilization of a refractory sample. Such a

means is provided by an adjustable sector disc, rotating in the path of light between condenser and slit and cutting off any desired fraction of the full illumination. The speed of rotation is immaterial so long as it is not so high as to set up excessive vibration. All that counts is the ratio of open to closed sectors.

Photography of the Spectrum—The photography of the spectrum differs in no essential respect from pictorial or metallographic photography. It is really somewhat simpler than either since the spectrograph is either permanently focused, requiring, with small or medium instruments, no adjustments to insure a sharp picture or, with the large size instruments but the setting of a couple of scales to predetermined figures to bring any desired portion of the spectrum into focus on the photographic plate.

Plates are more generally used than films since they provide a more accurate surface on which to focus the spectrum. The slight curvature that is required to insure sharp focus over the full length of the spectrum can usually be applied to a plate without danger of breakage, and without any of the resultant lateral curvature that is apt to distort the spectrum when films are used.

Almost any of the commercial photographic emulsions can be used. Ordinary plates are satisfactory for the ultra-violet and the short wave portion of the visual range. Panchromatic plates must, of course, be used when it is necessary to record longer wave lengths, up to the red end of the visual spectrum. Specially sensitized plates are now available which extend the range that may be photographed well beyond the visual region into the infra-red. Others make possible the photography of the short wave, ultra-violet in the region to which the gelatine of the emulsion is not transparent.

Slow plates are generally more satisfactory than fast ones as they have finer grain, and show better contrast and resolving power. Their slowness is not a disadvantage as it is usually necessary to give rather long exposures to permit time for the complete vaporization of the sample and thus to insure a correct indication of the proportions of the constituent elements, those that are highly volatile and come off rapidly from an arc as well as those that are refractory and evaporate more slowly. Exposures of 2 or 3 min. are usually required with small samples of metals in graphite electrodes. Slags and refractories may require 5-10 min. to insure complete volatilization. When metallic electrodes made from the sample material are used with the arc the case is somewhat different. It is impossible to insure the volatilization of a definite amount of material; long exposures may be accompanied by a gradual change in the proportions of constituent elements at the points where the arc has struck and short exposures will frequently yield more consistent results than long ones.

Qualitative Analysis—If the fully developed spectrum of a pure element is examined it will be found to include a number of lines of different wave lengths. With some elements the number is small, with others large. Some lines will be of high intensity, some weak, some exceedingly faint. If the spectrum is that of a material in which the given element forms only a part of the whole, other conditions being the same, the lines of that element will, in general, appear with decreased intensity. Those that were weakest in the full spectrum will fail to appear at all. At still lower concentrations other weak lines disappear until, at the lowest concentrations at which the element can be detected at all, only one or two lines remain. These are the so-called *raies ultimes*, the lines that are the last to disappear when the dilution is carried to the limit. De Gramont⁴ has made a thorough study of this phenomenon and has published a table giving for each of a large number of the elements, the wave lengths of these most persistent lines, together with a few which, while not so persistent as the *raies ultimes*, can still be observed at low concentrations.

In qualitative analysis, the identification of the elements present in a sample requires only a systematic search for these highly persistent lines of each element. It is not necessary to go through the tedious process of identifying every line in the spectrum. If the *raies ultimes* of an element are found, they provide proof of its presence in the sample. If they are absent, it is useless to look for other lines of the element in question, as they will certainly be missing.

The most convenient and at the same time the most certain procedure in qualitative work is to locate the lines in question by their positions in the spectrum

with reference to neighboring lines of known source and wave length, either in the same spectrum or in a standard spectrum photographed on the same plate adjacent to the one under examination. The iron arc spectrum is almost universally used as a standard, except in the case of spectra taken with instruments of low resolving power and dispersion. The iron spectrum contains many lines, well distributed throughout the range of wave lengths used in analysis. Therefore, convenient reference lines can be found near to those to be identified wherever they may be. Their wave lengths have been accurately determined and are available in published tables. They occur in groups that can readily be recognized after a little practice so that the experienced spectroscopist has little difficulty in locating and identifying the lines to be used as bases of reference.

Wave lengths of sufficient accuracy for most purposes can be determined by measuring accurately the distance on the plate between two reference lines, one on each side of the line to be identified, and also the distance between the latter and one of the reference lines. Knowing the wave lengths of the reference lines, simple arithmetical proportion gives that of the unknown. The computation assumes a linear relationship between wave length and line position. This of course is not strictly true in a spectrum taken with a prism spectrograph, since the dispersion increases with decrease of wave length. If the reference lines are not far apart, however, the error is small and the calculated wave length is usually close enough for correct interpretation. Occasionally it may be necessary to measure with greater precision than is attainable by linear interpolation. Such a case would arise when two or more elements had spectrum lines of so nearly the same wave length that the identification was in doubt and no other lines of these elements were available as a check. It would then be necessary to select three or more reference lines in the standard spectrum, measure their positions and that of the unknown line with the greatest possible precision, using an accurate measuring microscope, and compute the wave length with the aid of the Hartmann interpolation formula. Space does not permit a detailed discussion of this formula here, but it may be found in the larger treatises on spectroscopy.⁸ It involves rather laborious calculations to evaluate the constants in the equation for a given instrument and spectral region, but when properly applied gives results of the highest precision. A considerably simpler formula, giving very nearly the same results, has been suggested by Russell and Shenstone.⁹ A still simpler procedure that is more accurate than linear interpolation is the graphical method of plotting line position against wave length on co-ordinate paper, using a sufficiently large scale to permit readings to the required precision and enough known lines to define accurately the form of the curve.

A great deal of time may be saved by the spectroscopist who is doing much qualitative analysis, if he will prepare a diagram, similar to Fig. 3, for each element, when first he has occasion to identify it, noting the distances, as measured on his plates, between reference lines and those of the element involved. He will thus gradually build up an index that will enable him to identify the important lines by simple measurement, without having to repeat the calculations. An excellent precaution also is to list beside each diagram the wave lengths of lines of other elements that might be confused with the one under consideration with their distances from the same reference lines. This will serve as a warning if special care in measurement is required to insure correct identification.

Quantitative Analysis—As mentioned in the previous section, the intensities with which the lines of an element are brought out in the spectrum under constant conditions of excitation and photography bear a direct relation to the amount of that element present in the sample. When much is present, the most prominent lines are strong; when little is present all lines are weak. This provides the basis for quantitative analysis.

The excitation and photography of the spectrum are essentially the same in quantitative as in qualitative analysis. More care is required, however, to maintain constant conditions at all stages of the procedure, since there are many variables that may influence the densities with which lines are brought out on the photographic plate and these must be kept under control if results of reasonable accuracy are to be obtained.

Comparison of Spectrum Lines—All quantitative methods depend on the comparison of the densities of the spectrum lines of the constituents to be determined, with those of the same lines in the spectra of standard samples of similar general

composition but with different known amounts of these constituents. This comparison is sometimes direct, sometimes indirect.

The simplest, but at the same time, the least accurate way is to compare the spectrum of the sample directly with a series of spectra, previously prepared from the standards, noting among the latter the concentration at which the lines of the element in question are equal in density to those in the sample spectrum. The concentration in the sample is then assumed to be the same as that of the matching standard. If no exact equality is found the concentration is estimated between the two standards, one of which shows the lines a little stronger, the other a little weaker than those of the sample. With experience such differences can be estimated fairly closely and results accurate to 20 or 25% of the amount involved can be obtained. Sometimes this degree of precision is all that is needed as, for instance, when classifying mixed stocks of materials, or determining the general type of an alloy. Usually, however, a higher degree of precision is desirable.

Among the factors that are most difficult to keep constant in the procedure just described are those involved in the photography. Plates, even of the same brand, vary somewhat in their behavior. Composition and temperature of the developing solution may change, with the result that spectra on different plates may not be strictly comparable. These variations can be eliminated to a large extent by photographing standards and samples on the same plate. This, of course, increases the time required for making the analysis but materially improves the precision of the results, since all spectra will then have had the same treatment. It is the procedure specified in the methods adopted as tentative standards for the analysis of certain metals by the A.S.T.M. in 1935. While not so precise as the methods next to be described it yields results that may be relied upon to about 10% of the amounts involved and has the advantage that no accessory equipment is needed for density measurements.

Internal Standard Method—While the precaution of photographing sample and standard spectra on the same plate eliminates errors due to variations in photography, there still remains the possibility that variations in the light source may affect the accuracy with which the spectra can be compared. Line densities may be appreciably increased or diminished by changes in electrical conditions in the excitation circuit between exposures, or by variation, as in the solution method, in absorbing power of the graphite electrodes. Errors due to the former cause are largely eliminated by the "Internal Standard Method" of Gerlach and Schweitzer.⁷

This is an indirect method in which the lines of the elements to be determined are not compared directly with the same lines in separate spectra of standards, but with selected lines of another constituent in the same sample. It is necessary that this second constituent be present in constant amount in all samples of a given material, or that it vary in amount only as a result of the variation in the amount of the constituent to be determined. Evaluation is based not on the actual densities of the lines in question but on their ratio, which is correlated with concentration by preliminary calibration with standards. For example, given the problem of determining the manganese in a steel, the iron content will be essentially constant in all samples of a given type, and therefore the iron lines in the spectrum can be used for comparison with the manganese lines. A preliminary calibration is first made by photographing the spectra of three or more samples which have been accurately analyzed and are known to contain different amounts of manganese from the lowest to the highest that may be expected in that grade of steel.

One of the manganese lines is selected which shows a suitable intensity variation over this range of concentration. It must not be a very strong line because beyond a certain density there may be too small a change in density with concentration to give good results. Likewise it must not be too weak, for a similar reason. The line should be one having a density that falls within the straight line portion of the characteristic curve of the photographic plate, the curve connecting light intensity and the density of the image produced by it on the plate. A fairly close approximation to this requirement is obtained if the line selected is clearly defined throughout the range and is distinctly gray, not black at the highest concentration.

From the many iron lines in the neighborhood of this manganese line one is selected to serve as the basis of comparison. It should have a density within

the range of the series of manganese lines. However, instead of showing variation in density throughout the series, this iron line will be of practically the same density in all, since the amount of iron is practically the same in all the samples. This line should be fairly near the manganese line in the spectrum since the rate of variation of density with light intensity is different at different wave lengths. In a typical series the manganese line in the spectrum of the sample of lowest manganese content will be considerably weaker than the iron line; at some higher concentration the two will be of approximately equal density, while at the highest concentration the manganese line will be stronger than the iron line. It is these ratios that are to be correlated with concentration, not the actual densities. In this way compensation is secured for variations in the light source. If all conditions could be kept absolutely the same during the series of exposures, there would be no need for the reference lines and the densities of the manganese lines could be used as a measure of concentration. Fluctuations are unavoidable, however, but since they affect both the manganese and iron lines to the same extent the ratio will remain practically constant, even though the actual densities differ.

The line densities are then measured with some form of density comparator or microphotometer. Several forms are used. One typical form uses the spectrum plate as a "lantern slide" and projects a magnified image of the portion of the spectrum containing the lines to be measured on a screen in the center of which is a narrow slit through which light can pass to a photocell. The image of the line to be measured is brought into position over this slit, so that the light reaching the sensitive surface of the cell is only that which has passed through the line on the plate. A galvanometer connected with the cell is deflected by an amount proportional to the cell illumination, that is, to the transparency of the line, and the deflections are read on a scale conveniently mounted in the front of the instrument. If any appreciable background of continuous spectrum is present on the plate it is necessary to allow for it by taking a reading in this background near to the line and expressing the line density as the difference between the two readings.

In each spectrum the two lines, manganese and iron, are measured and the ratio of the corrected readings is plotted against the corresponding concentration on coordinate paper. A curve is then drawn connecting the observed points. This curve, then, provides the means for determining the manganese content of any sample of the same type of steel.

Logarithmic or Wedge Sector Method—Another method of measuring line intensities is that using the logarithmic wedge sector or logarithmic spiral to vary the exposure over the length of the slit. This is an opaque disc, the periphery of which is cut in the form of a spiral, the difference between the shortest and longest radii being equal to the length of the slit. When this is properly mounted in front of the slit and rotated, one end of the slit receives light continuously during the entire time of exposure. Successive elements in the length of the slit receive shorter and shorter exposures, until at the other end they are but instantaneous flashes at each revolution of the disc. The result is that strong radiations are recorded on the plate as long wedge shaped lines while weak ones produce short lines, the length being determined by the proportion of the total slit length that receives sufficient illumination to produce a developable impression on the photographic plate. Line intensities are then read by measuring the lengths of the lines. This method has come into considerable favor since it requires no special instruments to measure intensities, and the readings can be made as soon as the plate has been developed without waiting for fixing, washing, or drying, thus saving an appreciable amount of time when speed is important. Its principal limitation is the uncertainty in determining the point at which the line ends, where it is gradually fading out to zero density. Uncertainties in measurement are sometimes reduced by using, instead of a continuous spiral disc, one cut as a series of steps so that the line appears on the plate as a series of clearly defined segments, the densities of which vary from one end to the other. Another device is to cross the slit with a "gridiron" of fine wires or opaque rulings regularly spaced on a transparent plate, the result being to break up the line into distinct segments. In either case the length of the line is measured by counting the number of segments or breaks that can be seen. The "internal standard" method of comparison is used with these devices as well as in the procedures depending on photometric measurements.

Metallographic Polishing

By J. R. Vilella*

Sampling—The metallographic specimen, like any other sample, to be of value must be truly representative of the parent metal, both as to chemical composition and physical condition. If it is not, the finest polishing, etching and photomicrography are wasted effort. Generally the purpose of the investigation and the shape and condition of the material suggest the position from which the specimen or specimens should be cut, but there are some general rules which, if observed, help to obtain adequate specimens:

1. If the object of the investigation is to determine the cause of a failure, the specimen should be obtained from a position close to where the failure was initiated. It is also advisable to obtain one or more specimens from a position some distance from the failure in order to compare the structures of sound and failed metals. Comparisons of this type usually yield valuable clues.

2. When working with rolled or forged materials transverse and longitudinal sections should be examined. This is equally important whether the purpose of the examination is to study the nonmetallic inclusions or the structure. If the material has been cold reduced, specimens in the direction of working are indicated.

3. In wrought or wrought and heat treated materials it is advisable to include in the specimen a portion of the outer skin, so that decarburization and other surface conditions may be noted.

4. If the metal is suspected of segregations, several specimens from different positions should be examined.

Cutting the Specimen—When the location of the specimen has been settled, the specimen may be cut by means of a hack saw, a band saw, a cutting-off wheel, or in the case of hard and brittle materials, it may be notched and fractured. Occasionally it is necessary to resort to flame cutting in order to obtain suitable specimens from large sections.

Regardless of the means employed it is essential to avoid heating and dragging the metal at the cut surface. With hardened steel, heating is particularly undesirable because it is likely to temper. To minimize heating during cutting, a hack saw should be used, with proper lubrication, for all specimens that can be cut by this means. Hard materials should be cut with cutting-off wheels operating under water. Dragging of the surface metal is a common defect encountered in specimens of soft materials. It can be minimized by lubrication of the saw blade. The structure of a flame cut surface is, obviously, not representative of the metal, and therefore not a suitable metallographic specimen.

Specimen Size—Whenever possible, for convenience in subsequent handling, the size of the specimen should be within the limits of $\frac{3}{8}$ to 1 in. sq. (or dia.) and somewhat less in thickness. Smaller specimens are not only difficult to handle but almost impossible to polish without rounding the edges excessively. Larger specimens are difficult to finish without scratches and without dislodging the nonmetallic inclusions. Specimens in which the height exceeds the linear dimensions of the face to be polished are difficult to grind with the necessary flatness. It is not always possible, however, to get specimens of comfortable size. Sheet metal, wire and a multitude of other small articles are definitely of too small cross section to handle comfortably. These must be mounted either in clamps, molding plastics, or in fusible alloys.

Mounting of Specimens—The method to use depends on the purpose of the specimen, its shape, the maximum temperature it can stand without alteration of its structure and, of course, on the equipment available at the laboratory.

Steel clamps of adequate shape and dimensions are best adapted to rectangular and square specimens having straight edges. They constitute the most satisfactory means of preserving the flatness of the edges; in fact, they are almost indispensable, even when working with large specimens, when the edges are to be examined at intermediate or high magnification. In general, the degree of roundness of the edges is proportional to the difference in hardness (or abrasion resistance) between the specimen and the mounting material. For this reason, when maximum flatness of the edges of hard specimens is needed, even clamps, if made of soft metal, are not entirely adequate. In such cases the clamp should be made of a material which

*Research Laboratory, U. S. Steel Corp., Kearny, N. J.

approximates the hardness of the specimen. However, to obtain consistently satisfactory results certain other precautions must be observed. In the first place, clamps often interfere with the etching of specimens of dissimilar composition, as for example, stainless steel mounted in carbon steel clamps; secondly, their rigidity makes it difficult to obtain close contact between clamp and specimen, with the result that a trace of the etching reagent often creeps up and stains the edge it was desired to examine. A satisfactory way of overcoming these difficulties is to insert a strip of soft copper between the clamp and specimen. In this manner, a tight contact is produced without in any way damaging the edge, and at the same time the interference with etching is overcome, for copper is hardly attacked by the usual etching solutions for steel.

The use of fusible alloys as a mounting material, such as Woods metal, has, because of its tendency to smear and because of its inability to prevent rounding of the edges, been largely superseded by harder plastics such as Bakelite, Lucite and Tenite, which have proved invaluable to those handling a large number of small specimens.⁴ Their chief merits are: (1) Adaptability to specimens of any shape, (2) close contact between specimen and mounting material, so that staining due to seepage of the etching reagent is prevented, (3) relatively low molding temperature, permitting its use even for specimens subject to tempering, (4) inertness to the etching reagent, and (5) good, although not the best possible, preservation of the flatness of the edges.

Another practical and rapid method of mounting specimens in which optimum preservation of the flatness of the edges is not necessary is the following: Place a brass ring of convenient size, preferably one made oval by compressing its sides, on a smooth steel plate and pour inside the ring enough mercury to form a pool $\frac{1}{8}$ to $\frac{1}{4}$ in. deep. Push the specimen through the mercury, surface to be polished down, and hold in contact with the plate. Pour molten sulphur over the mercury and specimen, to fill the ring, and allow to solidify. This takes place rapidly. To recover the mercury, slide the assembly to the edge of the plate and collect it in a convenient receptacle. In specimens mounted in this manner the surface to be prepared is level with the walls of the ring but not in contact with it at any point and also at a considerable distance from the level of the sulphur; thus it can be polished without dragging the mounting material over the polished surface, and without contaminating the wheels with sulphur. The low melting point of the sulphur, its rapid cooling, and the fact that it never comes in contact with the immediate vicinity of the surface to be polished, minimizes the danger of altering its structure as a result of heating.

Preliminary Facing—This may be accomplished by filing, by grinding on stones or prepared papers or by machining. If filing is used, the best way to obtain a flat surface is to lay the file on the working bench and push the specimen against the cutting edges, preferably in one direction only, for back and forth rubbing tends to round the edges of the sample. More rapid and equally satisfactory results can be obtained with motor driven belt surfacers. These are not restricted to small specimens of soft materials, like files are, and when properly used, yield satisfactory flatness. Grinding stones are perhaps the least satisfactory means of obtaining a flat surface; they tend to fill up with metal, become dull in a comparatively short time, requiring frequent dressings and eventually develop grooves which round the specimen. However, with proper care, and in the hands of careful workers, these disadvantages can be largely overcome. Regardless of the means employed, care should be taken at this stage to maintain the specimen cool and to avoid deep scratches, for a deep scratch may completely alter the structure of the underlying metal. This condition has often been observed in specimens of 18-8 and other alloys susceptible to structural changes by comparatively slight cold working.

Grinding—Grinding consists of abrading the specimen with a series of grits of increasing fineness until a set of scratches is produced which is sufficiently fine to be totally eradicated in a reasonably short time with finest polishing material available. There are several satisfactory ways of carrying out this step.

1. *Grinding on Abrasive Papers*—This method consists of abrading the specimen with papers coated with aluminum oxide (emery) or silicon carbide (Carborundum) of increasing fineness. The grades most commonly used are 100, 200, 320 and 400 mesh grit; or No. 2, 1, 0, 00 and 000. This may be done either by hand or on power driven wheels. In either case, on passing from a coarser to finer paper it is advisable to rotate the specimen 90° so as to facilitate recognizing when the coarser scratches have been entirely replaced by the finer ones.

The chief merits of this method are that the nonmetallic inclusions are not dislodged, that it is comparatively easy to master and that the commercial grades of papers available are well graded as to grit size and are of uniform high quality. Its chief disadvantages are (1) that it distorts the structure of the surface metal, particularly when the papers are used after the grit has become dull, (2) that it tends to round the corners and edges of the specimens and (3) it tends to heat the specimen. However, these disadvantages can be greatly minimized by careful working.

Hand polishing is generally considered a slow and laborious process and for that reason is seldom practiced in this country. The technique of those who still use it consists of rubbing the specimen back and forth on abrasive papers stretched smoothly over a flat hard wooden block or a metal surface. Its advantages over machine grinding are less heating and less distortion of the surface metal.

In machine grinding, the speed of the wheels is of some importance. However, since the rate of cutting or abrasion depends on the linear velocity and not on the r.p.m., a higher rate of cutting is always obtained at the periphery than at the center, and likewise, the larger the disk the faster the rate of cutting at the periphery. For these reasons, recommendations as to the best speed of grinding expressed in r.p.m. are of little significance. It can be safely said that in practice high speeds are not conducive to the best results nor appreciably expedite the process. A speed of 600-700 r.p.m. for a 9 inch disk is used in the writer's laboratory. With well constructed machines free from vertical vibrations, higher speeds can be used safely.

2. Grinding on Paraffin Wheels—Disks similar to those used for grinding with papers are covered with a layer of high melting point paraffin about $\frac{1}{4}$ in. thick, machined flat and a spiral groove or a series of concentric circles $\frac{1}{8}$ in. deep inscribed on them by means of a nail or some other pointed article. The function of the groove is to hold the water and abrasive on the disk. The abrasives consist of a series of emery powders, ranging in fineness from 200 to 600 mesh, which are suspended in a soap solution and sprinkled over the revolving disks at frequent intervals. Natural emery is preferred.

An excellent modification of this method is to use instead of a paraffined disk, canvas or billiard cloth previously impregnated with paraffin. The paraffin is melted in a suitable container and the cloth immersed in it until it has absorbed all the paraffin it can hold. While the impregnated cloth is still warm and pliable it is stretched smoothly over the disk and held in place by means of a ring which fits around the circumference of the wheel. Billiard cloth is preferable for the finer abrasives and 12 ounce canvas for the coarser ones. At first the impregnated cloth will feel somewhat rough, but it will become smooth after grinding several specimens.

The merits of this method are: (1) Satisfactory preservation of the nonmetallic inclusions, (2) good flatness of the edges of the specimens, (3) less distortion of the surface metal than is produced by grinding on papers, and (4) the specimen does not heat up during grinding.

3. Grinding on Lead Laps—Two methods^{2,3} involving the use of lead laps have been described recently. Both are based on the principle that grit held firmly by the carrying medium, that is, not free to roll during grinding, does not excavate the nonmetallic inclusions, nor widens any cracks or porosity which may be present in the metal. One of these methods, originated in Sweden, is as follows: On each of three disks is deposited a layer of lead approximately $\frac{1}{4}$ in. thick and machined flat. The abrasive (emery or tungsten carbide) is applied and "fixed" to the lead lap with a fast drying varnish previously thinned with benzene. The grinding procedure is carried out in three steps after preliminary "coarse" grinding to obtain a flat surface, (1) grinding with emery of 100-40 microns in grain size, (2) grinding with emery of 50-25 microns size, and (3) grinding with tungsten carbide of grain size less than 4 microns. It is important that the surface after the preliminary grinding be as flat as possible, for if rounded the process is greatly delayed in the subsequent step, inasmuch as the lead lap cuts only in one plane. After the grit has become dull through grinding it can be "resharpened" by simply passing a brush dipped in benzene over the disk; this softens the varnish and causes the abrasive grains to turn, thus presenting a new sharp face to the specimen. The varnish rehardens in about one minute.

The advantages claimed for this method are: (1) Rapid preparation of the specimen, (2) a degree of flatness not obtainable by any of the usual metallographic polishing methods, (3) excellent preservation of the nonmetallic inclusions, (4) the

possibility of using finer abrasives and hence shortening of the time required for the final polish, and (5) lower operating cost than with abrasive papers.

The other method¹ utilizing lead laps was originated at the Bureau of Standards. It is carried out in two steps, but each step requires two disks, one for the actual grinding made of 50% lead and 50% tin alloy; and the other disk is made of high strength, fine grain cast iron, used only for charging and maintaining the flatness of the lead-tin disk.

The cast iron disk is ground in a precision surface grinder to a maximum deviation from a true plane of 0.0001 in. over the entire surface. The disk contains grooves $\frac{1}{2}$ in. apart, milled to a depth of $\frac{1}{32}$ in. with 60° milling cutter, and it is somewhat larger than the lead-tin disk. The lead-tin disk contains similar grooves but $\frac{1}{4}$ in. apart. The surface of this disk should be faced flat in a lathe before milling.

Charging of the lead-tin laps is accomplished by placing the emery of the proper grades (American Optical Co. No. 302 and 303½) mixed with water on the face of the cast iron disk and rotating the lead-tin disk, face down, upon it for about 30 sec. It is then brushed and washed until free of loose grit.

Grinding is done using water as a lubricant. Only a very gentle pressure is needed to obtain good cutting action. The advantages of this method are the same as those claimed for the Swedish method.

An automatic polishing method⁴ employing cast iron and lead laps was also recently described. It is not discussed here in detail because it requires specially built equipment.

Rough Polishing—Rough polishing is merely the last stage of grinding but because it is the most important step in the entire process of metallographic polishing, it must be treated separately. On this step depend (1) the length of time required to finish the specimen, (2) the preservation or dislodgement of the non-metallic inclusions, and (3) the thickness of the layer of distorted metal which must be removed before the true structure is revealed. This step can be carried out in several ways, of which the most frequently practiced are the following: (1) Grinding on billiard cloth or canvas with powders such as 600 alundum, emery or tripoli; (2) grinding on fine abrasive papers such as No. 0000 or 600 grit emery or Carborundum; (3) grinding with 600 or finer emery on wax disks or billiard cloth impregnated with paraffin; (4) grinding with 600 or finer emery or tungsten carbide powder on lead laps.

(1) *Loose powders on billiard cloth or canvas* produce fine even scratches, which disappear readily during the final polish and yield a surface with a minimum of disturbed metal. Their main disadvantage is that the prepared surface is likely to be badly pitted as a result of the dislodgement of the nonmetallic inclusions. The method, therefore, is not recommended when the correct preservation of the inclusions is essential to the purpose of the examination.

(2) *Grinding papers*, such as No. 0000 or 600 emery preserve the nonmetallic inclusions intact, but cause a considerable distortion of the surface metal and yield scratches of uneven depth, thus frequently retarding the final polish. Finer and more even scratches can be obtained by using a No. 000 or 600 paper which has been partly worn by use and glazed by polishing on it a piece of graphite.

(3) *Grinding with 600 emery on wax or paraffined cloth disks* preserves the nonmetallic inclusions quite well, yields fine, even scratches which are removed easily during the final polish and do not produce an excessive amount of disturbed metal. This method represents an excellent compromise between the two methods previously discussed.

(4) *Grinding with 600 or finer powders on lead laps* is probably the best method of rough finishing so far developed. The inclusions are well preserved, the specimen possesses a degree of flatness not attainable by any of the other methods, the scratches can be made fine and even by judicious selection of the powder and by carefully avoiding contamination with coarser grit, and it does not produce excessive distortion of the surface metal. This method, however, is applicable only to specimens which have been ground very flat during the prior stages, for otherwise the rounded parts of the specimen will not come in contact with the abrasive and consequently will not be acted upon.

The Final Polish—This step is generally carried out on a soft cloth with either levigated alumina, rouge, magnesia or other equally fine finishing powders. The selection of the finishing powder is a matter of individual preference, for equally good results can be obtained with any of them, provided they have been properly

levigated. The writer prefers alumina because it is the cleanest to handle and because an excellent grade can be purchased already levigated.

The type of cloth to use depends on the purpose for which the specimen is being prepared. If it is desired to obtain the best possible preservation of the nonmetallic inclusions, or the graphite flakes in cast iron, then it is advisable to use a hard, pileless fabric, such as the dull side of a heavy silk satin, or a good grade of heavy cotton or linen cloth, for it has been observed by many experienced metallographers that the softer materials, such as broadcloth or "kittens ear", exhibit a pronounced tendency to dislodge the inclusions. On the other hand, the soft fabrics are preferable when the structure of the specimen is to be examined or photographed at high magnification, for these fabrics produce fewer and smaller scratches.

It would be of little value to make precise recommendations as to the optimum speed to use for the final polish, because experience has shown that satisfactory results are possible at a wide range of speeds. However, the consensus of experienced metallographers is that best results are obtained at low speeds. At the author's laboratory a speed of 280 r.p.m. for a 9 in. disk is used.

Defects of Polished Surfaces—The defects most frequently found in metallographic specimens are: (1) Scratches, (2) rounding of the corners and edges of the specimen, (3) pits resulting from dislodgement of the nonmetallic inclusions, and (4) distortion of the surface metal.

(1) *The avoidance of scratches* is a question of cleanliness, and careful levigation of the finishing powder. Some of the most common causes of scratches are dirty hands, grit under the finger nails, abrasive from the previous operations on the sides of the specimen and contamination of the finishing fabric with flying grit from other wheels. The remedies suggest themselves; proper levigation of the finishing powder, careful washing of the specimen and hands, particularly before attempting to give it the final polish and keeping the wheels well covered when not in use.

(2) *The flatness of a specimen*, as was pointed out before, depends on the method of polishing and on how it is mounted.

(3) *The prevention of pits* resulting from dislodgement of the inclusions has already been discussed. It will be well to state here, however, that a pitted surface gives an exaggerated impression of the amount of "dirt" in the steel, and that as a result of improper polishing many a satisfactory heat of steel has been branded "too dirty". It is treading on dangerous ground to rate a steel as dirty unless one is sure that the inclusions are preserved intact.

(4) *Distortion of Surface*—Of all the defects of a polished surface, the most misleading, common and subtle is the inevitable distortion of the surface layer brought about when a malleable material is ground with a hard abrasive. It can be said without exaggerating that the greatest progress made in metallographic polishing during the last ten years, is the recognition of the existence of this distorted layer and its elimination by the method of alternate polishing and etching to be described. While some methods of polishing produce less distortion than others, the writer knows of none yielding an undistorted surface. It is well to assume, therefore, that the structure revealed by etching a highly polished surface is not the true or undistorted structure of the metal. The question now is, how can the true structure be revealed? The writer knows of no more dependable way of accomplishing this than the following: The polished surface is given a normal etch and its structure noted under the microscope using the dry objective of highest resolving power available. It is then repolished on the final wheel, reetched and reexamined. The process is repeated as long as changes in the appearance of the structure are noticed. As a rule two or three repolishes suffice, but occasionally, particularly when working with soft metals, more may be necessary. In general, the softer the metal the greater the distortion, but even hard metals are never polished completely free from distortion. Attempt to short cut the process by deep etching generally results in pitting and obliteration of the finest details of the structure.

Summary—The perfectly or ideally prepared specimen must possess at least the following characteristics: (1) It must be truly representative of the metal both as to chemical composition and physical condition. (2) It must be sufficiently flat, from edge to center, to permit examination at all points at all magnifications. (3) It

must be free from scratches, stains, and other imperfections which tend to mar its appearance. (4) It must contain intact all nonmetallic inclusions. (5) It must be free from all traces of disturbed metal.

Photomicrography

By J. R. Vilella*

The purpose of photomicrography is twofold; to procure permanent and accurate records of structures which are finer than the unaided eye can see, and to show others what we saw with the aid of the microscope. To accomplish this satisfactorily a photomicrograph must meet certain minimum requirements: I. It must represent the true structure of the metal. II. Its magnification and resolution must be sufficient to show clearly all significant detail. III. It must be technically correct photographically.

I. The True Structure of a Metal—It is of the utmost importance in the preparation of metallographic specimens to bear in mind that the attainment of a specular finish free from scratches does not necessarily constitute a satisfactory polish for photomicrography. Frequently, the structure revealed by etching a highly polished surface is not the true structure of the metal but merely that of a layer of metal which has suffered considerable distortion as a result of polishing. The true or undistorted structure lies below this layer and will not be seen until all traces of distorted metal have been eliminated. As is to be expected, the softer the metal the deeper the distortion, but even hard metals are susceptible to this effect. It is well, therefore, to expect distortion in all polished surfaces and to make certain of its elimination before a photomicrograph is made. For a more detailed discussion of this subject see the article on Metallographic Polishing.

Likewise, a specimen is not ready to be photomicrographed until it has been correctly etched. Correct etching consists of (1) selecting the reagent best suited to the chemical composition and physical condition of the metal, and (2) etching to produce the proper degree of contrast, which depends on the element of the structure which is to be emphasized and on the magnification at which it is to be photographed. Obviously, an etched surface exhibiting stains, etching pits or uneven attack is not correctly etched.

What reagent to use is entirely a matter of experience. If any doubt exists, several of the reagents tabulated in the article on Etching Reagents should be tried and the photomicrograph made after etching with the reagent which most clearly reveals the true structure, for that is the best reagent for the specimen at hand.

The depth of etching, or degree of contrast produced in the structure is of great importance in photomicrography. While it is not possible to give a set of instructions covering all cases, observance of the following will be found helpful:

1. Etch no deeper than necessary to bring out the significant detail.
2. A degree of contrast satisfactory for low power photomicrography is generally excessive for the best possible definition of the structure at high magnification.
3. If high contrast is desired, it is preferable to obtain it by photographic means rather than by deep etching, for deep etching obliterates the fine details of the structure.
4. If a specimen is insufficiently etched (too low contrast) it is preferable to repolish on the finishing wheel and to re-etch, rather than to superimpose one etch on the other.
5. Do not touch an etched surface with anything, and photograph soon after etching.

II. Magnification and Resolution—Given a properly polished and etched specimen the first question to decide is the magnification and the objective to use in making the photomicrograph. There are two rules concerning magnification which are sound but not inflexible:

1. Photograph at the lowest magnification which shows clearly all significant detail.
2. To obtain from a given objective the maximum amount of detail (resolution) and the sharpest image, maintain the magnification between the limits of 400-1000 times the numerical aperture (N.A.) of the objective.

A magnification of at least 400 N.A. is needed by a person of normal vision to distinguish all the detail resolved by the objective. This magnification, however, barely renders visible the finest detail and consequently is not comfortable to look at. At higher magnification the detail becomes easier to see, but at the same time the image loses sharpness. It is necessary, therefore, to arrive at a compromise. It has been found through experience that 1000 N.A. is as high as it is possible to go and still have an image of acceptable sharpness when achromatic

*Research Laboratory, U. S. Steel Corp., Kearny, N. J.

objectives are used. However, photomicrographs have been made with apochromatic objectives of the highest quality at better than 1500 N.A. which appeared acceptably sharp when viewed at a distance of 10 inches from the eye. It must be borne in mind, however, that to produce a sharp photomicrograph at even 1000 N.A. correct polishing and etching are essential, and all other causes of defective images must be absent.

A magnification in excess of 1000 N.A. necessarily involves a considerable degree of empty magnification but it is justified when the photomicrograph is to be viewed from a distance, as by several observers simultaneously.

Resolving power is the property of a lens which enables it to show distinctly separated two elements of the structure which lie close together, as for example, the lamellae of pearlite. The degree of fineness of detail which an objective can reveal, that is, its resolving power, increases directly with its numerical aperture, but the fact that an objective of high N.A. possesses high intrinsic resolving power does not necessarily mean that it will resolve a given fineness of detail under all conditions. It merely means that it will resolve that detail if properly used. It is important, therefore, to examine those factors under the control of the metallographer which affect the resolving power of an objective.

In the first place, the specimen must be correctly polished and etched for not even the objective of the highest N.A. will show clearly a structure in which the detail has been deformed or obliterated by poor polishing and etching. In addition the following factors must be considered: 1. Proper adjustment of the illuminating system. 2. Optimum opening of the aperture diaphragm. 3. Wave length of the light used. 4. Method employed to illuminate the specimen.

1. Proper adjustment of the illuminating system is essential because otherwise the image produced can be misleading. It is not possible, however, to make definite recommendations for the correct setting of the illuminating system owing to the varied design of the microscopes in use throughout the metal industry. It must suffice to say that failure to maintain the illuminating system adjusted in strict accordance with the instructions given by the manufacturer of the instrument invariably leads to some loss of resolving power.

2. Because the image produced by microscope objectives, particularly those of high N.A., is not always as flat as would be desirable, many resort to expediency of "stopping down" the aperture diaphragm of the microscope in an effort to secure a larger area in focus, a practice which is equivalent to cutting down the N.A. of the objective and therefore its resolving power. High power objectives cannot always be used at full aperture because of the interference of "flare," or internal reflections, but there is an optimum opening for every objective at which flare is not objectionable and which should be determined by the metallographer to enable him to use the objective at its highest practical resolving power. Lack of flatness of field can be partly remedied by the use of negative oculars designed specially for that purpose, but never at the sacrifice of resolution. A small field with maximum resolution is preferable to a large flat field lacking resolution.

3. The resolving power of an objective is higher the shorter the wave length of the light illuminating the structure. For maximum resolution, therefore, the shortest wave length for which the objective is adequately corrected should be used, that is, yellow-green for achromatic and blue-violet for apochromatic objectives. This is the principal function of light filters in ferrous metallography because the structures are seldom highly colored, but in nonferrous metallography, where brightly colored structures are not uncommon they are also used to bring about a more accurate tone rendition of the colors. Inasmuch as photographic emulsions are not equally sensitive to all colors, it is often necessary to filter out or partly suppress some of the wave lengths to which the emulsion is most sensitive in order to reproduce photographically the correct relative brightness of the colors.

4. Modern metallurgical microscopes are generally equipped with plane glass vertical illuminator, prism illuminator, dark field illuminator, polarized light, and with adjustments designed to produce the effect known as conical illumination. The plane glass vertical illuminator is the type generally used in photomicrography because it permits obtaining from the objective all its resolving power. In most microscopes it is placed in a fixed position at the factory and requires no further adjustment from the metallographer.

The prism illuminator is supplied for two purposes: As a means of obtaining oblique lighting and to provide brilliant illumination for dark structures, and for projection. Because they utilize only one half of the pencil of light, they cut the resolution of the objective in half, this loss of resolution occurring only in the direc-

tion at right angle to the edge of rotation of the prism. They are intended only for low power work.

Dark field illumination is characterized by the fact that a reflecting surface lying perpendicular to the axis of the objective and illuminated by converging rays reflects no light into the microscope and consequently appears dark. Any part of the structure which is not perpendicular to the axis of the objective reflects into the microscope some of the light which strikes it and appears brightly illuminated. This method of illumination has several distinct advantages over ordinary bright field illuminations: (1) Inasmuch as the objective is not used as a condenser, as is the case in bright field illumination, there is less "flare" or internal reflections and the objective can be used at full aperture; (2) extreme contrast (black and white) can be obtained when desired; (3) it permits the examination of surfaces which are not so highly polished as is necessary for bright field; (4) it frequently renders visible detail which either through lack of contrast with the surrounding material or through insufficient resolution cannot be seen under bright field illumination; and (5) colored structures are shown in their natural colors.

The use of reflected polarized light in metallography is discussed fully in another article in this Handbook.

Conical illumination is a means of illuminating the structure obliquely without sacrificing resolution, as happens when the prism illuminator is used for the same purpose. The relief it produces imparts to the image a natural appearance, serves to differentiate between parts of the structure which under axial illumination appear identical and makes fine detail easier to see. Conical illumination, if properly used, yields evenly illuminated photomicrographs of high resolution and very pleasing to the eye.

Most microscopes are provided with a second iris diaphragm known as the illuminated field diaphragm, which is so placed in the microscope that its image is focused on the surface of the specimen when the specimen is in focus. Because of its position, this iris does not affect the resolving power of the objective, but it will be observed that as it is closed down the fully illuminated field becomes smaller and the contrast and sharpness of the structure improves perceptibly. For photomicrography, whenever the size of the illuminated field is larger than the plate or film, the iris should be closed down until the diameter of the fully illuminated image is equal, or less, than the diagonal of the photographic plate. This is especially important in high power photomicrography.

III. Photographic Technique—For a photomicrograph to accomplish its purpose it must show the structure with sufficient clearness to convince the observer that it is a faithful reproduction of the structure. A photomicrograph which because of technical imperfections lacks clearness, generally defeats its purpose and serves to cast doubts rather than to convince the observer.

The photographic plates or films best suited for photomicrography are those possessing the following characteristics:

1. High sensitivity to yellow and green light, that is, they must be orthochromatic. (All emulsions are sensitive to blue light; only panchromatic emulsions are sensitive to red light.)
2. Sufficient exposure latitude to yield properly exposed negatives without the necessity of close estimation of the exposure time. This is necessary because the intensity of the arc light generally used in photomicrography fluctuates considerably even while the exposure is being made and because the reflectivity of the various parts of the structure vary widely depending on their polish, composition and degree of etching.
3. A fine grain emulsion so that it can record accurately extremely fine details. (Photographic emulsions also possess "resolving power"; in general, the finer the grain the smaller the detail which can be recorded in a photograph.)
4. An effective antihalation backing is also important since the latitude over which the emulsion can reproduce accurately the finest details will be considerably shortened by the presence of halation.

The correct exposure is that which places the brightest and darkest portion of the structure within the limits of the latitude of the emulsion; that is, the brightest parts are not over exposed nor the darkest under exposed. Considering that the emulsions used in photomicrography are of the "short scale" type, it can be readily seen that the greater the degree of contrast produced by etching the more accurate the exposure needs to be. Indeed, it occasionally happens that the contrast produced in the structure through over etching is so great that even though it can be encompassed within the latitude of the negative, it exceeds that of the printing paper which is always less, and therefore a good print cannot be made. After all,

a negative is only a means to an end, that being the achievement of a perfect print. It is for these reasons that care should be taken to avoid etching with excessive contrast.

Whenever there is doubt as to the correct exposure, an exposure test can be made as follows: The entire plate is given an exposure estimated to be somewhat on the short side, let us say 2 seconds, and then the dark slide is pushed in approximately one inch and another exposure made of the same duration. The slide is then pushed in another inch and exposed again, but this time for 4 seconds, and the process repeated until a set of exposures, each double the preceding one, is obtained.

It helps to secure negatives of uniform quality from day to day to standardize the developing practice. The time temperature method (tank development) lends itself to standardization better than the tray or inspection method, and should be preferred. The developer recommended by the manufacturer should always be used. The length of time that a plate should be developed depends on the degree of contrast desired, for contrast increases with the developing time, provided that the temperature and agitation are constant.

Proper fixing and washing are also important. An active fixing bath containing an effective hardener is sufficient, provided that the temperature of the bath does not exceed 75°F. Above this temperature there is danger of the emulsion softening and reticulating. To prevent this in hot weather, it is advisable to use a "short stop" hardening bath consisting of 2% chrome alum and 2% sodium bisulphite. The hardener should be freshly prepared and used between development and fixing, leaving the plate in it for 3-5 minutes with the light off. The negative should then be fixed for at least twice the time required to clear it and washed in running water for 30-60 minutes. Insufficiently washed negatives deteriorate in a short time.

Correct printing in photomicrography consists of reproducing on photographic paper all the detail that the negative was able to grasp and in reproducing this detail in the proper tone relations. It consists essentially of two operations: (1) Choosing the grade of paper to fit the contrast of the negative, and (2) choosing the exposure which will print through the densest part of the negative which must show detail. To accomplish this, photographic papers are available in several grades of contrast. The low contrast or "soft" papers are for use with high contrast negatives and the "hard" or contrasty papers with "flat" or soft negatives. While these various grades can be obtained in a variety of surfaces the glossy finish is generally used in photomicrography because the smoother the surface the larger the scale of contrast reproduced by a photographic paper.

Summary—All that can be done in photomicrography is to reproduce the significant detail and tones of the structure as faithfully as possible. This can be accomplished as follows: (1) By polishing the specimen in such a manner that the true structure will appear on etching. (2) By etching to a depth or degree of contrast that does not obliterate detail and can be reproduced photographically. (3) By adjusting the microscope correctly so that maximum resolution may be obtained. (4) By an exposure which produces an image within the latitude of the plate or film. (5) By the development of this image to a contrast that fits the scale of the printing paper. (6) By the use of a paper that has the longest possible contrast range.

For photomicrographic illustrations and a more detailed discussion of the various points emphasized in this article, see the A.S.M. publication "Metallographic Technique for Steel" by J. R. Vilella.

Radiography of Metals

By Kent R. Van Horn†

Introduction—X-rays are a form of radiant energy or electromagnetic waves which were first detected by Roentgen in 1895, and are frequently called Roentgen rays in honor of the discoverer. The latter name is used in Germany, while the term X-ray is more prevalent in France, England, and the United States. The X-rays are similar in many respects to light and other radiation of the electromagnetic spectrum in that they travel in straight lines, traverse through space without transference or intervention of matter, affect a photographic film, and are not influenced by either electrical or magnetic fields. The various electromagnetic vibrations differ essentially in wave length, the gamma rays emitted during the disintegration of radio-active elements are the shortest,* then the X-rays, followed by the ultra-violet, the visible, infra-red or heat rays, television, radio, and finally the extremely long waves of electricity. The shorter wave lengths are generally less absorbed by matter and are consequently more penetrating. Gamma rays emanating from radium or its associates having a wave length of from 0.005-1.4 Å (1 Å = 10^{-8} cm.), and X-rays ranging from 0.06-1019 Å penetrate material which is opaque to visible light having a wave length of from 3800-7700 Å.

Light is transmitted through different types of glass with varying degrees of ease. Similarly, X-radiation is absorbed differently by various substances of greater or less density, that is, all materials do not possess the same degree of X-ray transparency. The absorption coefficient of X-rays is roughly proportional to the density of the absorbing medium. (More precisely, the absorption co-efficient increases with the atomic number of the absorbing atoms, the number of atoms per unit volume and the X-ray wave length.) Consequently a sound section of steel will absorb more radiation than a similar section of aluminum or organic tissue. It is possible, therefore, to locate inclusions differing appreciably in density from the surrounding material. These relations are the basis of the expanding science of radiography which may be defined as the nondestructive testing of matter with radiant energy (either X or gamma rays). The experimental procedure consists of passing radiation through the specimen and detecting the various intensities of the emergent beam by a photographic film or fluoroscope screen. The film is used for metals, while the fluoroscope is frequently employed in the examination of nonmetallics.

Probably the first practical application of X-rays was radiography, and today it is an invaluable test for medical and industrial diagnosticians. In 1922, 200 kilovolt peak, 8 m.a. X-ray tubes were available which could penetrate three and one-half inches of cast steel. This has been increased to five and one-half inches of rolled steel with 400 kilovolt peak, 5 m.a. apparatus in 1938. Reasonable quantities of the shorter wave length gamma rays can penetrate ten inches of steel. The present article will be confined to X-ray radiography. However, much of the individual discussion of general technique and interpretation apply to the gamma ray.

Generation of X-Rays, and Apparatus—It is known that X-rays are produced when matter is bombarded by a rapidly moving stream of negatively charged particles (electrons), that is, when the electrons are suddenly stopped by matter. A part of the kinetic energy is converted to energy of radiation (X-rays). In addition, the absorption of X-rays by various materials is accompanied by the emission of secondary radiation.

The essential conditions¹ for the generation of X-rays are: (1) Source of electrons (cathode rays) proceeding toward the target; (2) a target (anode) located in the path of the cathode rays; (3) a means of applying a potential difference between the cathode and the target which will give the requisite velocity to the electrons during the passage of the intervening space so that when they bombard the target the necessary X-rays will be propagated.

The first two requirements are incorporated in the X-ray tube which may be of two types. The first is a gas (ion) tube where the source of electrons is a mass of rarified gas that is ionized. The second (electron) type is a highly evacuated glass bulb or cylinder containing one or, in special tubes, two tungsten wire

†Metallurgical Division, Aluminum Research Laboratories, Cleveland.

*The cosmic rays have a shorter wave length than the gamma rays but their nature is controversial as they may be electro-magnetic waves or electrically charged or neutral particles.

filaments which emit the cathode rays and either a button, solid, or hollow target. The electron type is universal for industrial radiography and may range in capacity from 85-400 kilovolt peak. The lower voltage tubes have a fine focus and are generally air cooled while water or oil cooling and larger focal areas are characteristic of 300-400 kilovolt peak tubes. Radiographic tubes may or may not be self rectifying.

The third condition, a difference in potential, for the original apparatus was obtained by a direct current electrostatic generator, while later the ideal but expensive and dangerous source, a storage battery was utilized. However, today the high tension a.c. closed core transformer is used for industrial installations. Accessory equipment for the transformer type of power consists of: (1) An auto transformer for the control of the high tension transformer input; (2) a means of current rectification from a.c. to d.c., either valve tube or mechanical type (the valve tubes are replacing the older mechanical type); some of the recent installations are equipped with the newly developed self rectifying tubes and therefore do not require d.c. current; (3) a device for regulating tube current; (4) separate transformers for supplying the filament current of the X-ray and valve tubes. Additional windings on the high tension transformer or insulated storage batteries are also satisfactory as a filament supply; (5) instruments for measuring voltage such as a calibrated primary transformer voltmeter, electrostatic voltmeter, sphere gap, or spectrometer.

The radiographic units may be classed according to portability: (A) Permanent type where the location of the apparatus is fixed; (B) portable type of equipment that may be moved throughout the plant with comparative ease. The more recent installations are generally portable and are compact. Thus a complete oil immersed 300 kilovolt peak, 10 m.a. power plant and X-ray tube can be contained in a shock proof case 6 x 4 x 4 ft. suspended on trunnions on a movable truck.

It is imperative to protect the operators or any persons in the vicinity of all types of apparatus from both primary or secondary X-radiation because of the injurious effects. This may be accomplished by adequate thicknesses of dense materials which are impervious to X-rays, such as lead and concrete or fencing off a generous area around the temporary location of a portable set.

Methods of Detecting X-Rays—X-rays are detected by their effects on matter, which may be visible and either temporary or permanent. In addition, X-rays are revealed by induced physical and chemical changes which may be made permanent. Thus X-rays have been detected by an ionization chamber, fluorescent screen, photographic film, plate, or paper. Inasmuch as the film is generally used for industrial radiography, the other methods will be only briefly mentioned.

Vapors and gases such as SO_2 , ethyl bromide, and methyl iodide are readily dissociated by X-rays but difficulties are encountered in measuring only the ionization and not secondary effects. Tedious manipulation is required, and further, the average intensity over an entire region is measured which is not indicative of the variations from point to point. An ionizable chamber would be unsuitable for revealing small defects in large castings.

The visible fluorescence excited by X-rays on screens of calcium tungstate, or barium platino-cyanide, is utilized for medical examination, but only to a limited extent for the inspection of metals. Fluorescent screens vary in the brilliancy (glow) corresponding to different degrees of transparency of the exposed object, so that the dense structures causing less glow appear darker, which is the reverse of the effect on the photographic film. The fluoroscope offers the advantages of speed and economy but unfortunately does not integrate X-ray energy as does a film emulsion, and therefore much larger quantities of radiation are required to penetrate the same specimen. Furthermore, the record is temporary and the sensitivity is very inferior, ranging from $\frac{1}{5}$ - $\frac{1}{10}$ of that of a film.

An X-ray paper is marketed which costs about one-half that of a film and differs in several significant characteristics. The contrast of the paper is 40% less than the film, and the range of useful densities (latitude) is also materially less because of the reflection of some light from the surface. However, X-ray paper may be satisfactory for special cases, as the examination of a large number of similar parts where previous tests with films had indicated that objectionable defects would be adequately disclosed.

X and gamma rays, similar to light, produce a latent image on a photographic emulsion which is permanent and reproducible. Films designed especially for X-ray service consist of two thick sensitive layers, separated by a cellulose acetate

base that is, dupletized, and have more contrast than a single emulsion. (Photographic plates are not used because of inconvenience and their inability to be satisfactorily dupletized.) The image registered on the negative is dependent on the variations in absorption of the X-rays by the object and on the characteristics of the silver bromide emulsion. The important qualities of films are contrast, latitude, and speed. As the exposures for industrial radiography are relatively long, compared to medical work, the speed encountered in the films of today does not vary sufficiently to warrant consideration. The radiographic sensitivity (the minimum variation in thickness, or density detectable in a specimen) is the greatest with high contrast emulsions. However, with maximum differentiation of detail (contrast), the range of useful film intensities (latitude) is diminished. In other words, a high contrast emulsion will reveal minute defects in a certain section but would sacrifice satisfactory exposure of regions of appreciably greater or less thickness. Sufficient latitude will allow for unavoidable variations in exposure and development, also reasonable differences in thickness. Generally, emulsions that possess a compromise of contrast and latitude are desirable, although for some conditions requiring extraordinary sensitivity, high contrast may be selected.

Films are developed and fixed by the tank method in X-ray solutions designed to give extreme contrast and negligible chemical fog. The contrast³ is sensibly maximum from 5-9 min. development in standard X-ray solutions at 65°F. As the density (film blackening) increases with developing time, the exposure may be reduced by prolonging the latter. Thus with an 8 min. development, the exposure time may be decreased by 30% of that required for a 5 min. developing period.

Accessory Equipment—Negatives should be viewed for interpretation with a source of diffuse illumination which will reveal detail in areas of extreme blackening. The density of the film does not affect the visual sensitivity with a variation in illumination ranging from 5-3000 ft. candles. About 1000 ft. candles are recommended; this is obtained with either the 200 or 250 watt blue or argon lamps that are supplied in the commercial illuminators.

Film blackening may be precisely measured by a microphotometer. A density difference of 2% is considered the standard minimum value of detection. The usable densities range from 0.4-1.5 (standard density scale units), but detail is perceptible as high as 2.0. A film density of 0.7 frequently serves as a relative standard for comparing technique.

Improvement in contrast and a decided reduction of exposure time can be obtained by employing intensifying screens. A screen consists of an intensifying compound, usually calcium tungstate and infrequently zinc silicate, or zinc sulphide or barium platino-cyanide, coated with a cellulose binder on a cardboard support. On exposure of calcium tungstate or similar material to X or gamma rays, a visible and blue-light are emitted to which a film emulsion is highly sensitive, thereby accelerating the exposure effect. Two screens, one in front and the other behind the film, are generally used, although superior definition but less speed is procured with only one. Thick calcium tungstate layers are more efficient³ than thin, while the back screen may be even thicker than the front but not to the extent where its own light will be absorbed. The particle size of the calcium tungstate is also critical, as coarse grains increase the speed, while fine grains are more conducive to sharpness (definition). Intensifying screens maintained at low temperatures are extremely fast,⁴ as exposures at 40°F. are 33% less than at 70°F.

Zinc sulphide has recently been investigated because the speed with exposures below 100 kilovolt peak is greater than that of calcium tungstate (about twice as fast at 40 kilovolt peak).

Metal foils, particularly lead, and sometimes copper or aluminum, slightly decrease the exposure period and improve the quality of the negative. A lead foil filter (about 0.005 in. thick) placed on each side of the film will reduce fogging by absorbing some of the secondary radiation. The definition is also enhanced by the resulting fine grained image.

Intensifying screens must be handled carefully as they are brittle, expensive, and scratch easily. Dirt or blemishes on the sensitive surface are readily recorded on the negatives and complicate the interpretation.

The speed of the various materials may be compared by their intensifying factors, that is, ratio of exposure without screens to that with screens for a radiograph of standard density developed under normal conditions. The intensifying factor² of calcium tungstate is about 100 with 150 kilovolt peak X-rays and 2 for

gamma rays. The ratio for lead foil ranges from 2-6 between 100-200 kilovolt peak.

Sensitivity of Radiography and General Technique—The minimum perceptible variation in density (sensitivity) within a specimen is a measure of the over-all accuracy of the radiographic method. The sensitivity may be expressed as the smallest thickness of discontinuity (defect) in inches that is revealed on the radiograph or as the percentage of the total thickness examined which the smallest defect detectable represents. Of the factors that affect sensitivity, some may be controlled, while others are permanent limitations imposed by the apparatus. A discussion of the variables will indicate a general preferred technique although the details such as the specimen arrangement, exposure time,* or film processing should be obtained from the literature references.

The type of target of the X-ray tube, the material supporting the target, the size of the focal spot, and the method of rectification influence the sensitivity and cannot be altered.⁵ The higher the atomic number of the target metal, the more penetrating (shorter) the wave length of the X-rays although this is accompanied by decreased contrast. If the target is not solid metal but a button imbedded in a supporting conductive metal, extraneous radiation of different wave lengths may also be emanated from the surrounding metal which may approach 10% of the total if not removed by filtering. The focus of the X-ray tube is not a point source but occupies a fixed area. Consequently, the smaller the focal area the better the definition and the less the distortion. Rectification units of the same peak kilovolt capacity have dissimilar wave length distributions (mean voltages), thereby generating different proportions of long and short wave lengths which affect the quality of the beam.

Among the important factors affecting sensitivity which can be regulated is the quality of the radiant energy. The radiation emitted from the tungsten target tubes, which are generally used, varies over a considerable range of wave lengths (quality) and is related to the voltage applied to the tube. As the potential increases from about 89-200 kilovolt peak the wave length of maximum intensity decreases from 0.138-0.062A with a corresponding reduction in contrast and sensitivity.⁶ The smallest detectable difference in density has been demonstrated⁴ to be a straight line function of the voltage when plotted on a semilogarithmic scale. However, the shorter wave length X-rays are required for the penetration of 2-5½ in. of steel. Consequently, it is desirable to employ the lowest potential which will penetrate a certain thickness in a reasonable period of exposure.

The sensitivity is dependent on the wave length of the X-rays and the nature of the exposed matter excluding the fogging effect produced by scattered (secondary) radiation. Secondary radiation consists of primary X-rays that are scattered through wide angles with no change in wave length and X-rays of longer wave length characteristic of the absorbing substance generated by ejected electrons. The quantity of secondary radiation increases with the applied voltage⁶ and the number of atoms encountered (thickness of the material). The secondary energy derived from the specimen and surrounding objects fogs the film, thereby diminishing the sensitivity. Fortunately this may be materially reduced by the use of Potter Bucky diaphragms,[†] lead or copper screens, and an increased exposure time.

Additional undesirable radiation causing fogging, but primary in nature, is that proceeding directly from the X-ray tube to the film without passing through the object. This can be eliminated by shielding technique, that is, placing lead shot and sheet or heavy (barium) plastic clay around the specimen so that there will be no portion of the film exposed directly to radiation. Suitable shielding or immersion in dense solutions** may be used to compensate for variations in sectional thickness or surface inequalities.

In the preceding section, criteria were described for procuring maximum sensitivity from accessory equipment, namely high contrast films and the proper type of intensifying screens.

*Exposure charts for various thicknesses of metals under different conditions are available.¹⁴ However, this data will not apply to all apparatus because of the difficulty in reproducing radiation with a pulsating potential and variations in films or screens.

†An industrial movable grid diaphragm has produced remarkable results with a 5 in. thickness of steel but requires a longer exposure time than normal.

**Various aqueous solutions of lead nitrate or acetate and ethylene iodide for steel, carbon tetrachloride or barium chloride for aluminum.

The geometrical relations of the focus of the X-ray tube to the film, the location, the size and orientation of defects also influence the sensitivity of radiography. Although the focal area is permanent, definition can be improved by increasing the tube-to-film distance. The greater the distance, the smaller the angle of exposure and the better the definition or sharpness. This relation is limited because of the corresponding increase in exposure time since the intensity of X or gamma rays, similar to light, decreases inversely as the square of the distance from the source of emission. Also, as the source approaches the film, the exposure angle is enlarged, which induces a nonuniformity of film density. It is therefore desirable to use the largest tube-to-film distance consistent with a reasonable exposure period.

Flaws may occur in any part of the specimen and may be oriented at any angle to the incident X-rays. As the defect-to-film distance is increased, or the diameter of the defect is decreased below 1 in., the actual sensitivity is proportionately diminished.⁷ Consequently, if imperfections are more likely to exist in a certain section of a casting, this location should be placed adjacent to the film during examination. The orientation of minute cracks, cavities or gross films is important and may necessitate several exposures at different angles so that cracks presenting too small a variation in thickness or composition for detection in one direction may be revealed in another where the path of the X-rays coincides approximately with its longitudinal axis.

It follows from the discussion of the various factors that the best sensitivity will result from employing a small focus tube, as low a voltage as possible, large tube-to-film distance, high contrast film exposed with intensifying screens with the scattered radiation and chemical fogging reduced to a minimum. Sensitivity data are available and indicate the limits that may be obtained parallel to the path of the X-radiation. The smallest detectable difference in thickness in inches for $\frac{1}{8}$ and 1 in. of steel was found⁷ to be 0.0039 and 0.0041 in. at 150 kilovolt peak, while at 200 kilovolt peak the values were 0.0049, 0.0052, 0.0057, and 0.0063 in. for $\frac{1}{8}$, 1, 1 $\frac{1}{2}$, and 2 in. of steel, respectively. The measurements illustrate the advantage of a lower voltage and the latter (200 kilovolt peak) when converted to per cent sensitivity range from 0.65% for $\frac{1}{8}$ in. to 0.31% for 2 in. of steel. A sensitivity of 0.41%, with 150 kilovolt peak is possible for 1 in. of steel, with laboratory precautions, although in industrial practice (higher potential) 0.8 to 1% is easily attained. Similarly a laboratory value for 2 in. of steel is 0.31%, while routine inspection should not exceed 1-1 $\frac{1}{2}$ %, and for 3 to 5 in. of steel at least 2% is expected. The significance of these results is that variations of composition or thickness causing less change in film density than the per cent sensitivity for a certain thickness will probably escape detection.

Interpretation of Radiographs—A radiograph is a shadow picture of material more or less transparent to radiation. The X-rays darken the film so that regions of lower density which readily permit penetration appear dark on the negative in comparison with areas of higher density which absorb more of the radiation. Thus, voids and cavities in metals are recorded as darker areas whereas heavy inclusions, such as iron scale or copper segregation in an aluminum alloy, register as a corresponding lighter region on the radiograph. The film therefore discloses conditions within the metal of different density or X-ray absorption which may be more or less than the surrounding material. The sensitivity values indicate the smallest variation in absorption that can be appreciated.

In the metal industry most of the radiographic installations are located in the foundry and the welding shop. Consequently, the general appearance on the radiograph of the familiar defects encountered in castings or welds will be described. In castings, differences in thickness due to the form and intentional cavities, as cored holes, are regions of low density and are revealed as darkened areas. Specimens containing variations in thickness caused by the unintentional absence of metal are also more transparent, resulting in darkening of the film. Excess metal and inclusions more dense than the base metal appear as light regions. The common casting defects of the latter two types may be recognized on the negative by the following characteristics:

1. Surface roughness appears as white or dark irregular areas with a smooth contour. The coloration depends on whether the surface protrudes or is depressed. The surface irregularities of a rough casting must be compared carefully with the radiograph and identified before an attempt is made to interpret the internal discontinuities.
2. Gas cavities, blow holes, and minute pinhole gas porosity appear as well defined spherical or rounded darkened areas.

3. Shrinkage, pipe and shrinkage porosity are represented by filamentary or dendritic dark regions of irregular dimensions and indistinct outline.

4. Misruns and cold shuts appear as very prominent darkened areas of variable dimensions with definite, smooth outlines where the metal failed to fill or unite completely before solidification.

5. Cracks are represented by darkened lines of variable width and are filamentary when derived from insufficient feeding or contraction (shrinkage) on cooling from the melt. Cracks originating from internal stress in solid metal are either angular or straight and are of more constant width.

6. Sand inclusions occur as gray to black spots of an uneven or granular texture with indistinct extremities.

7. Inclusions such as foreign material, segregation, oxide, and slag, in steel castings generally appear as dark regions of definite and smooth outline. In light alloy castings, copper or iron segregation and foreign matter of greater density than the base metal occur as well defined, white (opaque to the X-ray) areas.

The radiography of steel welds is confined primarily to boilers, pressure vessels, and pipe. The origin and interpretation of flaws have been exhaustively studied during the standardization of inspection methods, and a comprehensive survey is available.⁹ The defects in order of prevalence of occurrence in steel welds are: (1) Slag inclusions; (2) porosity; (3) cracks; (4) incomplete fusion between the weld and base metal or between two layers of weld metal. All the imperfections are less dense than steel and are recorded as darkened regions on the radiograph. With the exception of incomplete fusion which is represented by a dark line parallel to the scarf, of rather constant width and direction, the defects appear similar to their description for sand castings.

Radiographic Applications—In the metal industries, radiography has been largely restricted to the inspection of cast or welded products. The examination of worked metal such as forged, rolled, or drawn sections is very limited because of the uniformly dense structure and unlikely existence of flaws of sufficient size to cause a perceptible variation in film density. However, some forgings have revealed internal cracks, laminations, and inclusions, but the occurrence is too infrequent to warrant serious consideration of X-ray inspection. Therefore, the commercial value of radiography depends on the class of material to be tested. Apparatus has been installed in four types of organizations: (1) Manufacturers of boilers or pressure vessels and pipe for the testing of welds; (2) foundries for the inspection of castings and ingots; (3) army arsenals, navy ship yards, consulting laboratories, and universities for the examination of castings, welds, and miscellaneous products; (4) companies fabricating miscellaneous nonmetallic products.

The first (see Watertown Arsenal below) exclusively foundry radiographic equipment was installed in this country in 1927¹⁰ and each year has added to the list of casting companies who have discovered X-ray methods to be indispensable. Apparatus now exists in cast or alloy iron, steel, and light alloy foundries, and is primarily used (75%) for the development of casting technique and to a smaller extent for routine inspection. After a successful procedure has been established only occasional X-ray confirmation is necessary. This division of the work is natural because of the added cost of radiography. However, complete examination is warranted for highly stressed castings such as pipe valves or fittings for high pressure-temperature systems, heat resisting retorts, airplane crank cases, or shock absorbers. An outstanding application was the nondestructive testing of all pipe, fittings, and turbine shells for a 1200-lb. steam line of a large electric power plant.¹¹ After several years of service, no casting has failed although a considerable number were originally rejected because of the X-ray specifications. Frequently, when the production of a part is too small to justify the expense of a forging die and operation, castings determined by the X-ray inspection to be homogeneous and sound have been acceptable. A manufacturer has appreciably increased the service life of heat resisting furnace fittings, pots, retorts, and thermal protection tubes by radiographic researches.¹² Some indication of the value of radiography to this producer is that 2,000,000 sq. in. of film were exposed in the year 1937.

The ability of the X-ray to disclose the injurious defects in welds such as slag inclusions and porosity has been recognized by the Bureau of Engineering of the Navy, the A.S.M.E., and the American Petroleum Inst. In 1931, the A.S.M.E. Class I Boiler Code governing boiler drums and unfired pressure vessels permitted welded construction but required complete X-ray inspection of the seams. Welded construction of pressure equipment has progressed phenomenally since 1931, although little utilized previously because an efficient nondestructive test had not been available. Also, it is doubtful if the fusion welded structural developments

would have attained the popularity enjoyed today without the confidence reflected by the acceptance of welded boilers.

The impetus from the boiler industry, since 1931, has rapidly advanced the use of radiography so that there are now probably 5 welding installations for every foundry unit. In 1938, there were about 57 equipments distributed among 34 manufacturers and consumers of boilers and pressure drums. The six major companies, engaged in fabrication of pressure apparatus,¹³ have examined over 7,000 vessels representing approximately 161 linear miles of welded steel joints ranging in thickness from $\frac{1}{4}$ -5 in. All fusion welding of the penstocks of the power plant at Boulder Dam, totaling 21.6 miles of seam, was minutely inspected. This project alone required about 77,000 exposures consuming 1,500,000 sq.in. of film. Unlike the foundry, the majority of weld radiography is devoted to routine testing while a smaller portion is confined to the development of technique.

U. S. Army officials, visualizing the possibilities, installed the first equipment in this country for the radiography of cast and welded products in 1922 at Watertown Arsenal, Mass.¹¹ This was followed by apparatus at Rock Island Arsenal, Ill., and also interested other governmental divisions. The consulting laboratories¹⁴ and some universities have materially aided in the developing of X-ray technique and introducing new applications. The experience of these organizations include: Castings, welds, and nonmetallics.

The capacity of the X-ray to reveal variations in density has resulted in a number of interesting nonmetallic applications.¹⁵ Briefly, oil paintings have been radiographed to determine their origin or genuineness by art museums. Bakelite molds, candy, coal, carbon contacts, golf balls, rubber tires, tobacco, and tooth paste have been examined to detect foreign material or flaws. Many nontransparent assemblies such as broadcasting tubes, insulated wires, and closed cores are inspected to ascertain correct alignment of the internal components.

Gamma Ray Radiography—Gamma rays emanating from the disintegration of radio-active elements have experienced limited radiographic applications. The source may be radium, radon, or mesothorium, which emit considerably shorter and more penetrating wave length radiation than that of X-rays. It is estimated that the gamma wave length spectrum corresponds to X-rays that would be generated by potential of from 400,000 to 1,500,000 volts.

In addition, the gamma radiation differs from the X-rays in several pertinent qualities. As contrast diminishes with decreasing wave length or increasing voltage, the gamma rays are unable to reveal the very small defects in $\frac{1}{2}$ to 2 in. of steel. The gamma ray wave lengths are characteristic of the source and cannot be regulated for contrast or variable thickness. An advantage of the gamma radiation which improves the sensitivity is the small absorption and low scattering power resulting in appreciably less fogging than that produced by X-rays. The net effect of the two compensating factors, lack of scattering and low contrast, is that the sensitivity of the gamma ray is inferior to the X-ray for steel sections $\frac{1}{2}$ to 3 in. thick. The per cent sensitivity of gamma rays under laboratory conditions for $\frac{1}{2}$ -2 in. of steel ranges from 5-1.75% and for 3-6 in. is 1.3%.¹⁵

Other important considerations which limit extensive use of gamma ray radiography are the expense and time of testing. The rental or purchase of only a small quantity of radium is feasible which would require exposure of the order of 10-16 hr. to penetrate steel sections 2-5 $\frac{1}{2}$ in. thick. Although gamma rays are not directional but are emanated spherically so that many specimens may be simultaneously examined by suitable distribution about the source, the number of exposures for a specific time is relatively small compared to the large number that could be obtained with the X-ray in the same period.

The gamma radiation is attractive for applications where good definition, absence of apparatus and ease of arranging exposures are desired. (The technique has been developed and the details are described.^{15, 16}) Excellent definition can be procured by decreasing the dimensions of the source, that is, by reducing the quantity of radium or absorption of radon by a small piece of carbon. The simplicity of gamma ray technique is utilized for the radiography of steel castings and welded structures in an assembly or in service, inaccessible to X-ray apparatus. Frequently circumferential welds of pipe in a line are more economically examined by gamma radiation because of the number of films that may be simultaneously exposed from a single radio-active source and the inconvenience of moving or orienting the pipe for X-ray inspection. Also, companies not having sufficient nondestructive testing to justify an expenditure for an X-ray installation, rent radium occasionally. It

would seem that the gamma rays will not be used as extensively for industrial radiography as X-radiation but will be confined primarily to the examination of material opaque to the X-ray ($5\frac{1}{2}$ -10 in. of steel), inaccessible or inconvenient to the latter type of radiation. The two methods do not appear to be competitive but supplement each other.

X-Ray Diffraction

By Charles S. Barrett*

Introduction—A wealth of information on the structure of matter has resulted from the discovery of von Laue and his collaborators in 1912 that crystals act as suitable gratings for diffracting X-rays. The regular repetition of identical groups of atoms throughout a crystal forms a three dimensional grating which affects a beam of X-rays in much the same way that an optical grating affects a light beam. The repeating unit in a crystal, the unit cell, is a few Angströms in each dimension and is thus able to form a diffraction spectrum of X-rays which have a wave length of one or two Angströms. By directing a small beam of X-rays at a small sample of a substance and photographing the rays diffracted in different directions from it, the substance can be classified as amorphous, crystalline, or intermediate; the perfection of the crystal lattice can be determined; single crystals can be distinguished from polycrystalline substances, and the size of crystallites can be approximately determined; from the X-ray pictures supplemented by other data the crystal can be assigned its proper classification among the 7 crystal systems, the 14 space lattices (Bravais lattices), and the 32 point groups (symmetry classes), and the 230 space groups, and the positions in the unit cell of all atoms can be accurately determined, barring experimental difficulties or highly complex crystal structures. Additional information that can be read from the photograph includes the orientation of a single crystal and the preferred orientations in a polycrystalline specimen, the dimensions of the unit cell to a high degree of precision, qualitative and in some cases quantitative information on the intensity of internal or applied stresses, the effect of plastic deformation, of heat treatments, or of the mechanism of deposition, crystallization, transformation and precipitation on the lattice, and the constitution of organic and inorganic systems, minerals, and alloy systems.

The interpretation of the diffraction effects has been greatly simplified by a principle discovered in 1912 by W. L. Bragg. He pointed out that each of the diffracted rays could be interpreted as a *reflection* of the incident X-ray beam from a plane of atoms within the crystal. Given a parallel set of such planes of atoms repeating throughout the crystal and spaced at intervals of d , the condition for X-ray reflection from these planes is

$$n\lambda = 2d \sin \theta$$

where λ is the wave length of the X-rays, measured in the same units as d , n is the order of the reflection (always an integer), and θ is the angle of incidence of the beam on the planes, which is equal to the angle of reflection from the planes. This relation between the spacing of atomic planes, the wave length, and the diffraction angle, known as Bragg's law, and the optical reflection analogy on which it rests is the basis for interpreting almost all practical applications of X-ray diffraction.

Description of Apparatus for Typical Installation—X-ray diffraction installations are simpler than radiographic installations: They operate at a lower voltage, generally 30,000-60,000 volts; rectification of the high voltage is optional, and condensers and other filtering equipment to produce constant voltage direct current are unnecessary. Usually included in the installations are suitable overload relays, safety devices, switches, and meters for reading voltage and the current through the X-ray tube.

Both gas tubes and electron tubes are in common use, gas (or "ion") tubes operating at a critical gas pressure of about 0.01 mm. of mercury, with a cold cathode, and electron tubes operating at a high vacuum with a hot filament (usually a tungsten spiral). Tubes of both types may be made demountable so that targets of various elements can be interchanged at will and cathodes replaced when necessary. Electron tubes made of glass, highly evacuated and sealed off from the vacuum pumps, are widely sold. The sealed-off molybdenum target tubes are the nearest approach to a universal tube for commercial applications, for both monochromatic (characteristic) radiation and a considerable quantity of polychromatic (general) radiation is emitted, so that the tube can be used with fair success with nearly all methods. Sealed-off tubes require the minimum amount of

*Member of staff, Metals Research Laboratory, and Lecturer, Dept. Metallurgy, Carnegie Institute of Technology, Pittsburgh.

attention and skill in operating, but demountable tubes have the maximum flexibility and are required in many advanced research problems and in work of high precision. Gas tubes are preferable for work with powder methods because of the purity of the radiation. In electron tubes tungsten is slowly deposited on the target, and with improper vacuum technique mercury is also deposited, so that the pure spectrum of the target material may become contaminated with radiation from tungsten and mercury.

Complete units with tubes, transformers, and controls fully enclosed may be purchased from manufacturers. These permit from 2 to 12 cameras to operate simultaneously, and usually are supplied with sealed-off tubes having molybdenum targets. Demountable tubes of various types and many varieties of cameras may also be purchased. Exposures require varying lengths of time depending on conditions, usually between an hour and a day; zinc sulphide intensifying screens placed in contact with the film will reduce exposure times materially.

Laue Method^{1,2}—The Laue method uses a beam of X-rays containing many wave lengths. A system of pinholes confines a beam to a narrow pencil of rays which falls upon a small crystal or penetrates a thin crystal. The usual arrangement is for a photographic plate to be placed 4 or 5 cm. beyond the crystal and perpendicular to the original X-ray beam, film A in Fig. 1. (The film B is used

Fig. 1. Laue camera. Film A records the transmission pattern, film B the back reflection pattern, usually not simultaneously.

Fig. 2. Laue pattern (transmission type) with X-ray beam approximately parallel to a crystal axis of four fold symmetry. Undistorted crystal.

only for the back reflection method referred to below.) On the photographic plate the diffracted rays make a pattern of spots, as in Fig. 2, each spot being the reflection of a certain wave length from a certain crystal plane in one or more orders. The X-ray tube is best equipped with a target of tungsten and operated at 50,000-60,000 volts. The radiation emitted under these conditions contains a broad band of wave lengths (general or "white" radiation).

The diffraction spots are arranged on ellipses which have one end of their major axes at the central undiffracted spot. All the spots on any one ellipse are due to reflections from planes of a single zone (planes parallel to a common line known as the zone axis). As the spots are formed by rays of different wave lengths, their blackness depends not only on the arrangement of atoms in the crystal, but also on the intensity of the wave lengths in the X-ray beam, and on the sensitivity of the photographic emulsion to the different wave lengths.

The Laue method is useful for the determination of crystal structure. Indices may be assigned to the spots by various methods, the most convenient being the gnomonic projection. The symmetry properties of a crystal may be determined from the symmetry of the Laue patterns; when an X-ray beam passes through the crystal parallel to a four fold rotation axis, for example, the pattern will coincide with itself if given one quarter turn about the center (Fig. 2). The symmetry elements deduced from Laue patterns will always include a center of symmetry, whether or not the crystal possesses one. Large quantities of data on the

relative intensity of reflection of different planes can be obtained from Laue patterns when proper precautions are taken, and are of value in determining atomic positions in the unit cell.

The Laue method reveals imperfections resulting from accidents of crystal growth or from deformation.^{3,5} The Laue spots from perfect crystals are sharp, as in Fig. 2; whereas imperfect crystals or plastically deformed crystals produce blurred images and spots elongated radially as in Fig. 3 giving the appearance known as "asterism." An analysis of this can give the range of orientation of the reflection planes,^{3,6} and can indicate the severity of the deformation received by the specimen, but does not provide a reliable means of quantitatively measuring stresses.⁴ The Laue method is also useful for determining the orientation of single crystals.^{1,2} For this purpose the symmetry of the pattern may be noted or it may be plotted on a stereographic or gnomonic projection.

Back Reflection Laue Method—The most convenient arrangement for orientation work is the back reflection Laue camera, in which the film is mounted over the pinhole system, at B in Fig. 1, the film registering the rays that are diffracted back toward the X-ray tube. The analysis of back reflection Laue patterns for single crystal orientation is done by stereographic projection,⁷ and is too detailed for presentation here. Crystals must be reasonably perfect for this method, as the spots overlap and become indistinguishable if imperfections amount to more than two or three degrees.

The "Pinhole" Method⁸—The "pinhole" method is a combined Laue and powder method that is so often used in practical work as to deserve separate discussion. Because most practical applications of the pinhole method are simple and easily understood, they are presented before the powder method and will serve somewhat as an introduction to the latter. The apparatus is identical with that of the Laue method, except that radiation is not purely general (white), but also contains strong monochromatic components. Molybdenum target tubes are used, operating at a voltage of 30,000-45,000 volts and giving strong monochromatic (characteristic) lines at a wave length of 0.71 Angströms (actually a close doublet of this average wave length) and a weaker line at 0.63 Angströms, the $K\alpha$ and $K\beta$ lines, respectively. The specimens are polycrystalline materials—in the case of steel either wires or thin strips about 0.004-0.010 in. thick. Patterns from coarse grained materials contain many spots, as in Fig. 4. Throughout a series of exposures in a given camera, the size of the spots is proportional to the size of the grains and the number of spots is proportional to the number of grains per unit of volume of the specimen, provided the grains are smaller than the effective cross section of the X-ray beam. As the number of spots increases, circular diffraction rings appear (see following section). At first the rings are granular, but as the number of spots increases (that is, the grain size decreases) the rings become continuous and smooth. Just as in the Laue method, a lengthening of the spots, "asterism," is caused by crystal imperfection or plastic deformation.

Fig. 4. Pinhole pattern of undistorted polycrystalline material. Typical of recrystallized metal.

Fig. 3. Laue pattern of a distorted crystal, showing asterism.

The distribution of intensity around the diffraction rings reveals the presence or absence of a preferred orientation of the grains (fiber textures). Random orientations produce rings that are uniformly black all around; highly developed orientations give the appearance of Fig. 5, which is a tracing of a pattern from rolled steel. In the cold rolling of steel, preferred orientation begins to be detected at reductions of 20-40% in thickness and gradually increases in perfection until the pattern resembles Fig. 5 at 90-95% reduction.

Upon recrystallization, the rings break up into spots again and may or may not show the same intensity maxima. The preferred orientations after recrystallization have been analyzed in this way and some are found to be the same as in the

cold worked material, some new ones are found, and frequently the recrystallization produces a random orientation.⁹ The presence or absence of preferred orientations can only be determined if there are many spots in the pattern (more than in Fig. 4, for example) and in coarse grained material it is often necessary to shift the specimen during the exposure to provide a sufficient number of spots.

Fig. 5. Pinhole pattern (transmission) of sheet steel having a preferred orientation from cold rolling. (Rolling direction vertical, sheet surface perpendicular to the X-ray beam.)

A series of pinhole patterns taken with different angular settings of the specimen with respect to the beam is necessary to study all orientations of the grains. It is customary to plot the data from a series of exposures of this type on a stereographic projection;^{9, 10, 11} this plot (which is actually a map of the relative frequency of different orientations of a crystal plane) is known as a pole figure. Industrial problems frequently do not require such an extended study, and a single picture with the beam perpendicular to the strip or wire specimen often supplies all the required information.^{4, 7} Internal stresses and the recovery from a stressed condition are not readily shown with pinhole pictures.

A convenient arrangement for determining the depth of cold work produced by machining is to have the beam strike the specimen at an oblique incidence and reflect from the surface of the specimen, rather than penetrate it.^{4, 7} If the surface is cold worked, the spots will be blurred and may overlap into continuous rings, but after etching to a depth sufficient to remove the cold worked layer the spots become sharp. Back reflection cameras, discussed in the following section, are also much used for this purpose.

Powder Method^{1, 9, 12}—Radiation—The powder method employs monochromatic radiation falling on a powdered crystal specimen or a fine grained polycrystalline specimen. Radiation is obtained from X-ray targets of relatively low atomic number giving weak general radiation and relatively strong characteristic radiation. Molybdenum targets may be used but are not satisfactory unless a zirconium filter is placed over the photographic film in the camera. Best results are obtained by choosing targets of Fe, Co, Ni, Cr, or Cu, or alloys of these. The target is chosen so that the characteristic $K\alpha$ radiation is of longer wave length than the K absorption limit of the specimen in order to avoid fogging of the film by fluorescent radiation originating in the specimen.

Fig. 6. Powder camera (Debye-Scherrer-Hull)

Fig. 7. Focusing camera (Seeman-Bohlin, Phragmen).

Cameras—Powder cameras are of various types. The common Debye-Scherrer-Hull type (Fig. 6) consists of a cylinder on which is mounted the photographic film, a rod shaped specimen on the axis of the cylinder, suitable slits or pinholes to direct the primary beam at the specimen, and a device to catch this undiffracted beam or conduct it out of the camera after it has penetrated the specimen, thus avoiding intense blackening where it strikes the film. Focusing cameras are also cylindrical but are designed so that the specimen, the slits, and the photographic film all lie on the circumference of the cylinder (Fig. 7). This arrangement causes diffracted rays from all parts of the specimen to come to a focus on the film and give sharp lines with relatively shorter exposure time.^{9, 12} Back reflection cameras employ large angle diffracted rays only. They may be constructed with a cylindrical

film, with a flat film, or with a photographic plate (see B, Fig. 1); a hole is provided in the film or plate for the passage of the primary X-ray beam. Any of these types may be modified to operate with the specimen at either high or low temperatures, and for use with large grained samples they may be provided with devices to oscillate or shift the specimen in order to give more grains a chance to reflect the X-rays.

For studies of cold work and annealing, simple back reflection cameras serve well.¹ Co and Fe radiation are used for steel and copper specimens, and Cu radiation for aluminum specimens, to give a strong diffraction line at a large angle. The pinholes need not be as small as in cameras used for precision lattice constant determinations. Cold work is shown by a blurring of the spots lying on the diffraction rings and a broadening of the rings, as indicated in Fig 8 and 10. Recovery

Fig. 8. Pattern from distorted polycrystalline material in a back reflection camera (Film B, Fig. 1). Blurred spots form a ring surrounding the central hole in the film.

Fig. 9

Fig. 10

Fig. 11

Fig. 9. Powder pattern of annealed iron, from camera of Fig. 6, with FeK α and FeK β radiation. Increasing θ from left to right.

Fig. 10. Pattern from cold worked iron. Lines widened and weakened by "microscopic" internal stresses.

Fig. 11. Pattern from recrystallized iron, the large unstrained grains forming spotty lines.

from the strained condition is indicated by a sharpening of the lines (compare Fig. 9, annealed, with Fig. 10), and may or may not go on simultaneously with recrystallization, which is indicated by a return of the spotty type of pattern as in Fig. 11, indicative of large strain-free grains. This type of camera is not as useful for determining preferred orientations as the "pinhole" camera that produces its pattern in the forward direction.

The Diffraction Pattern—When a primary beam of X-rays strikes a specimen the diffracted beams leave the specimen along the generators of a number of cones, each of the cones being concentric with the primary beam. These cones fall on a flat film forming concentric circles, or on a cylindrical film forming curved lines, as indicated in Fig. 9. These are frequently called "Debye rings." From the diameter of the circles or arcs on the pattern and the known dimensions of the camera, the apex angles of the cones are calculated, and from these are obtained the angles of reflection, θ , of the Bragg equation. In the camera sketched in Fig. 1, with the film at A, if x is the radius of a diffraction ring, and X is the perpendicular distance from the specimen to film, then $\tan 2\theta = x/X$. In the camera of Fig. 1, with the film at B, $\tan (180 - 2\theta) = x/X$. In the camera of Fig. 6, if s is the circumferential distance from the central undiffracted spot to an arc of the diffracted line, and R is the camera radius, θ is given in radians by the relation $\theta = s/2R$ (1 radian = 57.30°); in practice, measurement is best made of the distance $2s$, from arc to arc, rather than s , from arc to central spot. In the camera of Fig. 7 (and frequently in the others also) it is convenient to prepare a calibration chart for reading θ or d directly from the positions of diffracted lines. A sample whose lines fall at accurately known angles provides the data for such a chart.

Thus, from the position of the lines on the film the spacing d of the corresponding atomic planes may be obtained. The sequence of lines on the film corresponds to the sequence of interplanar spacings in the crystal. The pattern in Fig. 9, for example, shows a sequence characteristic of body-centered cubic crystals. Large unit cells have all their interplanar spacings large, and thus their diffracted lines will lie at small angles from the direct beam, while small unit cells will have lines spread out at larger angles. It is the size and shape of the unit cell of a crystal

that governs the *positions* of the diffracted rays, while the atomic arrangement within the unit cell controls the *intensities* of the rays. The determination of crystal structure from the powder diffraction patterns is a complex procedure that yields a reliable result in only the simplest cases. Numerous summaries are available of the principles involved and of the various tables, graphs, and other devices to aid the investigator.^{1, 9, 11, 13}

Strictly monochromatic radiation is not usually available, for the targets of X-ray tubes emit radiation of a series of wave lengths, each of which forms a diffraction pattern on the film independently. The $K\alpha$ lines with closely similar wave lengths fall together and make a single line at low values of θ , but form a doublet at large values of θ (provided the specimen is able to yield sufficiently sharp lines). The $K\beta$ radiation, if not filtered out, produces another superimposed spectrum, which is of single lines instead of doublets and is always weaker than the $K\alpha$ spectrum. Its lines are recognized by these characteristics and by the fact that the ratio of $\sin \theta$ for $K\alpha$ and $K\beta$ radiations reflecting from a given atomic plane always equals the ratio of the corresponding wave lengths. The $K\beta$ radiation may be removed by filtering, if desired; zirconium filters are used for molybdenum radiation, and nickel filters for copper radiation. The filters are best placed between the specimen and the film.

Amorphous materials, glasses, liquids, and gases give only broad halos instead of sharp lines. Analysis of such patterns has nevertheless given a large amount of information of scientific and practical value.^{14, 15} Better patterns are obtained when a crystal monochromator is inserted in front of the powder camera to provide strictly monochromatic radiation, but exposure times are thereby increased several fold.

Precision Lattice Constants—The accuracy of lattice dimension measurement with the Debye-Scherrer-Hull cameras and focusing cameras is from 0.1-0.02%, depending on the care taken and the operator's skill. Back reflection cameras are more precise, for these will give from 0.02-0.003%. Sources of error which enter in determining lattice constants with Debye-Scherrer-Hull cameras include: Incorrect centering of the specimen on the axis of the camera, finite size of the specimen and absorption of the rays in the specimen, shrinkage or expansion of the film on development and afterwards, incorrect determination of the camera radius, lack of parallelism in the primary beam, and deviations from Bragg's law caused by index of refraction of X-rays. Corrections for these errors and for the errors in back reflection cameras have been carefully studied by numerous investigators.^{11, 16, 17, 18, 19}

Identification of Phases—A great number of practical problems require no crystal structure determination, but merely an identification of phases by their powder diffraction patterns, and this may be done without involved calculations by simply comparing patterns of the unknown material with patterns of chemically or mineralogically identified material.⁷ The films are laid side by side or superimposed, and the similarities are observed directly. For this work large range cameras are required, so that many lines will be obtained. If a large number of patterns from known materials are to be compared with the unknown, the comparison can best be made by first noting the position on the film of the strongest lines of each pattern.²⁰ For identification to be certain, every line of the pattern must be accounted for. Important advantages of this X-ray method of identification are that only small quantities of material are required (a few mg.), and that different compounds or states of combination of the same elements are distinguishable from each other, since they possess different crystal structures. Thus, chemical compounds are distinguishable from mixtures. The method is widely used for the identification of alloy phases; it is more direct and positive than metallographic methods, but generally is inapplicable when a phase constitutes less than 1-5% of the weight of the alloy.

If more than one variety of crystal is present in any specimen, each will produce its spectrum independently, and the pattern will consist of superimposed spectra with relative intensities dependent on the relative amounts of the two phases. If a series of alloys is prepared of various compositions spaced across a binary constitutional diagram, the powder patterns will follow the alternate single and two phase regions of the diagram.¹² Superimposed spectra from three or more phases may occur with alloys of more than two constituents, or in some alloys in which equilibrium has not been obtained.

Solid Solutions—The presence of solute contracts or expands the dimensions of the unit cell of the pure solvent material. This is registered on the powder photo-

grams by a displacement of the lines to either greater or smaller diffraction angles, unless the effect is too small to be recorded. The effect is ordinarily proportional to the atomic per cent of the dissolved element (Vegard's law) or closely approximates this. The expansion or contraction comes to an abrupt halt at the solid solubility limit, and throughout the two phase region beyond the limit the lattice dimensions remain constant in binary alloys. This behavior enables an accurate determination of the solubility limit (and its variation with temperature) and is preferable to determining the limit from the appearance of the lines of a second phase in the patterns.⁷ The method is applicable to determining the range of homogeneity of intermediate phases as well as solid solutions of elements, and is applicable (in altered form) to ternary alloys²⁸ as well as to binary alloys.

The following precautions must be taken in determining solid solubility:^{7, 28} A thorough homogenization treatment is necessary, for the specimen must be free from concentration variations; the surface must be free from sublimation, oxidation, or other reactions which would alter the surface concentration; if the specimen is to represent the condition of the alloy at the homogenization temperature, the quenching from this temperature must be sufficiently rapid to prevent changes, and yet quenching stresses must not be introduced into the specimen. These stresses can best be avoided by quenching small wires or finely powdered material. The precision of this X-ray method of determining solid solubility varies with different alloys, in many cases exceeding that of other methods.

The interstitial or substitutional nature of the solid solution can be determined from powder diffraction patterns. The patterns give the dimensions of the unit cell, and from these data, together with the number of atoms per unit cell, the atomic weight of each atom, and the composition of the alloy, the theoretical or "X-ray" density is computed—assuming either interstitial or substitutional dispersion of the solute; comparison of these calculations with the actual density will establish the nature of the solution.^{8, 11} X-ray and measured densities always agree within the limit of error of the measurements when the proper crystal structure has been assigned.

Solid solutions are ordinarily random arrangements of the different kind of atoms on the lattice points. When one kind of atom migrates to a particular set of atomic positions in preference to others, a superlattice is formed.^{8, 21} This is recognized in the diffraction pattern by the additional "superlattice lines" which appear after a suitable low temperature annealing treatment in certain alloys.

Stress Measurement—Internal and applied stresses in metals may be studied with powder diffraction cameras. When an interplanar distance d is altered by stresses the diffraction angle changes accordingly. If the elastic strain varies from grain to grain in a polycrystalline metal the angle of diffraction will also vary, giving a widened diffraction line in the powder photograph as in Fig. 10. The amount of widening beyond the normal width of an annealed stress free material indicates the amount of variation of stress from point to point in the metal, the relative intensity of "microscopic" stresses. Other factors than stress, however, may contribute to the widening and must be considered in interpreting the photograph;⁴ namely, inhomogeneity in composition of the specimen and small size of the reflecting grains. If stresses are of equal intensity in all the reflecting grains, forming a homogeneous stress system, the diffracted rays from all grains will superimpose to produce sharp lines displaced from their normal unstressed positions. The diffraction pattern can then be used to calculate the homogeneous "macroscopic" stresses.^{4, 7, 9} Back reflection powder cameras, arranged so that the X-ray beam falls perpendicularly upon the specimen surface, give data from which the sum of the two principal stresses lying parallel to the surface is calculated; cameras providing oblique incidence of the rays are used to calculate the principal stresses individually. An accuracy in stress measurement by these methods of 1,500-3,000 psi. has lately been attained with laboratory conditions and with favorable materials, but depends greatly upon the skill with which the operator attends to such matters as constancy of temperature of specimen and film, film shrinkage or expansion, provision that in both the stressed and unstressed conditions the specimen has the same solid composition, and preparation of the specimen so that the surface is free from a cold worked layer and is fine grained. The nature of the method is such that only stresses in the outer fibers of the specimen are observed, and it is not applicable to cold worked metals.

Rotating Crystal Method: Photogoniometers—Types of cameras seldom used in practical work, but indispensable in crystal structure determination, are those in

which a single crystal is mounted so as to oscillate or rotate around a definite crystallographic axis.^{1, 11} Monochromatic radiation is used, and the simpler cameras are similar to Fig. 6. Modifications of this are particularly helpful for solving complex crystals. The most common of these is the Weissenberg photogoniometer, which permits a photographic film to be shifted in synchronism with the oscillation of the crystal and is provided with a slit through which only selected rays from the crystal will pass. Spacings of the layers of spots in rotating crystal patterns give the distance between lattice points in the direction of the axis of rotation of the crystal. The assignment of indices to each of the spots is easily accomplished by graphical means derived from the reciprocal lattice projection.^{1, 11, 12} The orientation of single crystals may be determined with these types of cameras and also conveniently by the modification devised by Davey and outlined in detail by Wilson.¹³

Spectrometers—The most accurate method of measuring the intensity of diffracted rays involves the use of an ionization chamber mounted on a spectrometer somewhat similar to an optical spectrometer.^{1, 14} The current in the chamber, measured by an electrical device, is proportional to the intensity of the X-ray beam. The method is used in crystal structure determination, particularly with the newer technique^{1, 14} that involves Fourier analysis of X-ray intensities to yield almost directly the distribution of electrons and atoms in the crystal, but is seldom required in practical applications.

Chemical analysis is accomplished by X-rays through the use of spectrometers that photograph the characteristic X-ray emission lines or absorption edges of the sample to be analyzed.^{1, 15} Favorable combinations of elements permit extreme sensitivity in the detection of small percentages of an element in a compound or mixture (independent of its state of chemical combination), and, with care, fair precision in quantitative analysis is possible.

Summary of Applications and Methods Usually Employed

Preferred Orientations of Grains, Fiber Textures—Pinhole method, with beam transmitted through the specimen or reflected from the surface of the specimen, noting intensity maxima around Debye rings (Fig. 5).

Cold Work and Recrystallization—Pinhole method with transmission or back reflection cameras (Fig. 4, 8).

Identification of Phases—Powder method with cameras having a wide range of reflection angles (Fig. 9).

Precision Lattice Dimensions; Boundaries of Regions in Phase Diagrams; Studies of Solid Solution and Aging—Powder methods with precision back reflection cameras.

Grain Size—If larger than 10^{-3} cm., pinhole method or powder method, noting size of spots (Fig. 4, 11). If smaller than 10^{-3} cm., powder method, noting widths of lines (Fig. 10).

Perfection of Lattice in Grains—Pinhole, Laue, or back reflection powder methods, noting sharpness of spots.

Homogeneous (macroscopic) Internal Stresses or Applied Stresses—Precision back reflection powder method, with measurement of lattice dimensions.

Heterogeneous (microscopic) Internal Stresses and Recovery—Back reflection powder method, noting width of lines.

Orientation of Individual Grains—Laue, back reflection Laue, or rotating crystal methods, or photogoniometer.

Determination of Crystal Structure—Powder method only in very simplest cases; rotating crystal or photogoniometer method frequently supplemented by Laue patterns.

Structure of Amorphous Solids, Glasses, Liquids, and Gases—Powder method or spectrometer.

Chemical Analysis—Photographic spectrometer, registering emission lines or absorption edges.

Heat Treatment of Metals*

By R. S. Archer*

Introduction—The purpose of this article is to present certain fundamental principles which are applicable to the heat treatment of all metals—ferrous or nonferrous. Another article will deal more with the heat treatment of iron and steel, giving facts and figures relating particularly to the treatment of those materials. These articles, general in nature, are intended to serve as a foundation for specific articles describing the heat treatment of certain parts, such as gears and dies, and of certain nonferrous alloys. It is hoped that the need of repeating fundamental principles in the subsequent specific data sheets may be avoided by referring to these general data sheets.

Heat treatment is defined as an operation or combination of operations involving the heating and cooling of a metal or an alloy in a solid state for the purpose of obtaining certain desirable conditions or properties.¹

It is usually desired to preserve as nearly as possible the form, dimensions, and surface of the article being treated.

General Principles—The desirable changes in conditions or properties may be considered as due to changes in structure. Changes in internal stresses are frequently objects of heat treatment. Usually it is desired to decrease or relieve such stresses, although occasionally it is desired to set up stresses of a definite kind. Changes in internal stress are associated with changes in interatomic spacing. Hence, even stress changes can be considered as due to changes in structure if we regard interatomic spacing as one of the elements of structure.

More frequently, the changes effected by heat treatment involve changes in the nature, form, size, or distribution of the structural constituents. Changes in the nature of the constituents result from the effect of temperature on phase equilibria or from changes in the composition of material, as in the case of carburizing or nitriding. The form of constituents is affected by the conditions under which they separate from solid solutions, and by the tendency to assume equiaxed shape at temperatures which permit diffusion and atomic rearrangement (spheroidizing). Changes in the arrangement or distribution of constituents in a solid metal can be brought about by solution and reprecipitation, as when the granular cementite of an annealed tool steel is converted to the lamellar cementite of pearlite by normalizing.

Factors in Heat Treatment—Heat treatment consists of subjecting a metal to a definite time-temperature cycle. The chemical effect of the medium surrounding the metal may be of importance, as in carburizing and in nitriding. The time-temperature cycle may conveniently be divided into three parts: (1) Heating, (2) holding, (3) cooling.

Heating—The rate of heating determines the changes within the metal during this phase of the heat treatment, and the heating medium is important insofar as it affects this rate, and causes or prevents chemical changes, such as oxidation, proceeding from the surface of the metal. It is necessary to consider not merely the average rate of heating, but the rate of heating desirable or permissible at each stage of rise in temperature. In any case, the rate of heating is seldom constant and usually decreases as the final or holding temperature is approached, so that this temperature can be attained more accurately and uniformly.

The heat actually consumed in the practical heating of a metal to a given temperature is equal to the heat content of the metal at that temperature,² less the heat content of the metal at the beginning of the heat treatment operation, and plus the heat losses due to radiation during the heating process. These heat losses increase, other things being equal, with the duration of the heating operation.

From the standpoint of its effect on the metal, rate of heating may be important

*Chief Metallurgist, Republic Steel Corp., Chicago.

Prepared for the Subcommittee on the Heat Treatment of Metals. The membership of the subcommittee was as follows: R. S. Archer, Chairman; J. P. Gill, W. G. Hildorf, G. C. Lilly, W. B. Price, C. T. Willard, and E. S. Davenport.

¹See definition of "Heat Treatment" in this Handbook.

²See "Heat Content of Metals" in this Handbook.

insofar as it affects internal stresses, distortion, grain growth, or chemical changes such as oxidation.

If a piece of metal initially free from internal stresses is heated uniformly, no internal stresses will be set up. If the heating is not uniform, so that different parts of the piece acquire different temperatures at a given time, internal stresses will be set up which will cause distortion and in brittle metals may cause rupture. Uniform heating is favored by uniform application of heat, slow application of heat, and high heat conductivity of the metal itself. Particular care is required in the heating of brittle metals having poor heat conductivity, for example, hardened high speed steel.

The extent of normal grain growth is determined chiefly by maximum temperature and the time at or near the maximum temperature. Abnormal grain growth or germination, however, may be affected by rate of heating. A tendency toward germination is apt to be present in metals which have been work hardened slightly rather than severely, or in metals in which there are marked variations in the degrees of work hardening from one point to another. When such conditions exist, it is frequently possible to prevent or minimize abnormal grain growth by heating the metal very rapidly above the germinative temperature, which usually means heating rapidly to well above the temperature of recrystallization.³

Surface changes resulting from contact with the heating medium are naturally less during the heating cycle, other things being equal, the shorter the duration of this cycle. Rapid heating obtained by the use of a strongly oxidizing and active flame, on the other hand, might result in more oxidation than a slower heating with a more neutral flame.

Holding at Heat—Usually a certain time period, more or less definite, is required at the maximum temperature of the heat treatment. First, the time must be sufficient to permit the entire article to come to a uniform temperature, except in the comparatively rare cases where a nonuniform distribution of temperature is desired, as in the localized hardening of steel. Time to attain uniform temperature increases with the thickness of the heaviest section of the piece and is greater the lower the thermal conductivity of the material. The rate of heating employed must also be considered, since with slow heating a fair degree of uniformity may exist shortly after the metal has come to temperature.

The next requirement is that the time at heat be sufficient to allow the desired changes to take place within the metal. Most of these changes involve diffusion, and, in the case of wrought metals, grain growth. The solution of constituents such as carbides in steel depends upon diffusion away from the particles of such constituents. The conversion of combined to graphitic carbon in the annealing of malleable castings involves the diffusion of carbon from the carbide particles to the graphite nuclei. Case carburizing involves the diffusion of carbon from the surface toward the center.

Grain growth does not occur to any appreciable extent on reheating cast metals which have not been subjected to plastic deformation after casting, except in the case of iron and its alloys, which undergo recrystallization on heating through Ac-3'. Metals which have been plastically deformed, either hot or cold, exhibit grain growth at temperatures above what is known as the temperature of recrystallization. It is this grain growth which is responsible for the softening of work hardened metals on annealing. Grain growth is therefore not only desirable but necessary in the annealing of cold worked metals for the purpose of softening. Occasionally a very large grain size is desired, as in the treatment of certain metals for strength at high temperatures. In general, however, it is desired to limit the development of large grains since excessive grain size leads to various undesirable properties. Since both diffusion and grain growth require atomic mobility, these processes usually occur within approximately the same range of temperature. In the heat treatment of steel, it is commonly desired to bring about certain structural changes which depend upon diffusion, and to avoid as far as possible the grain growth which is apt to occur in the same range of temperature.

It is thus evident that the laws of grain growth and diffusion play an important part in the determination of temperature and time at heat.

³Science of Metals, McGraw-Hill Book Co., p. 136.

⁴See the article "Iron-Carbon Diagram" in this Handbook.

Recrystallization temperatures for certain metals after severe cold plastic deformation are given in the following table:

Recrystallization Temperatures^a

Approximate Lowest Recrystallization Temp., °F.

Iron	840	Magnesium	300
Nickel	1110	Tantalum	1830
Gold	390	Tungsten	2190
Silver	390*	Molybdenum	1650
Copper	390	Zinc	Room temperature
Aluminum	300	Lead	Below room temperature
Platinum	840	Tin	Below room temperature
		Cadmium	About room temperature

*Indications are that under certain conditions silver will recrystallize at lower temperatures.

These temperatures are higher the less the degree of cold working. Time is also a factor, and recrystallization can be brought about at temperatures which are lower the longer the time allowed at temperature. Impurities raise the temperature of recrystallization. For example, brass requires a slightly higher temperature than copper.

Grain size normally increases with both temperature and time of exposure. At a given temperature an apparent equilibrium grain size is eventually reached which does not change greatly on further increase of time. The time required to attain this condition may be a few seconds at temperatures just under the melting point, and a matter of days just above the recrystallization temperature. In practical heat treating the temperature is usually high enough to permit fairly rapid approach to grain size equilibrium, so that temperature rather than time is the more important factor governing grain size. In general, however, time is sufficiently important so that the duration of a heat treatment is not prolonged unnecessarily beyond the time required to produce whatever other changes in structure are desired.

The rate of diffusion increases rapidly with temperature. It also depends greatly on the nature of the dissolved substance. In most cases it seems that the dissolved substance diffuses in atomic form, and rapid diffusion is perhaps opposed by large atomic volume. Carbon diffuses rapidly in iron at temperatures above A₁, while phosphorus and certain other elements diffuse very slowly, even at much higher temperatures.

The time required to bring about a certain change involving diffusion depends not only on the rate of diffusion, but on the distances through which diffusion must take place. The time required is, therefore, longer the coarser the initial structure of the material.

Metals and alloys which are elastic at ordinary temperatures are left in a state of internal stress by all commercial cold working processes. High internal stresses can also be produced by uneven temperature changes. Rapid cooling, uneven sections, and mass contribute to such stresses. Severe stresses are set up in steel by the hardening operation, both by uneven temperature changes in themselves and by the volume changes incident to hardening and aging.

The reduction of internal stress by heat treatment is dependent on a slight plastic flow which is allowed to take place by the lowering of the elastic limit at the temperature at which it occurs. It is probable that any metal must be heated to a temperature near its recrystallization temperature to remove stresses; heating to higher temperatures will result in more complete removal. The extent to which stresses are removed is greater the higher the temperature and the longer the time of heating. It is well to keep in mind that even after internal stresses have been substantially removed by heating at a relatively high temperature, new stresses may be established during cooling.

Sometimes the object of heat treatment is best attained at temperatures just under the melting point of the most fusible portions of the material. This is apt to be the case where the effect desired depends on bringing into solution one or more constituents whose solubility increases progressively with temperature up to the point of incipient fusion, as in the hardening of high speed steel and duralumin. Occasionally materials of this class can be heated to such a temperature that some fusion takes place and then, either with or without subsequent treatment, they may have desirable properties. As a general rule, however, it is not safe to heat treat at temperatures which cause any fusion within the material.

^aScience of Metals, McGraw-Hill Book Co., p. 86.

When the object or one of the objects of heat treatment is to bring about certain phase changes in an alloy, there are rather definite temperature limits within which the desired change can take place. The permissible range of temperature is defined by the constitution diagram of the alloy. The selection of the most desirable temperature within the permissible range is influenced by the considerations mentioned above regarding grain growth, diffusion, and internal stresses, as well as by other practical considerations concerning distortion, scaling, and operating economy.

Above the recrystallization temperature metals deform plastically under low stresses. Objects undergoing heat treatment, therefore, may deform under their own weight or from any means of handling which imposes even fairly low stresses on the material. Low temperature and short time oppose the distortion of objects under their own weight, and low temperature minimizes distortion. Special means are often employed to hold articles in shape during heat treatment. Castings may have members cast into them solely for this purpose, such members being cut out after heat treatment. Fixtures may be employed in the heat treating furnace to prevent sagging at the high temperature. Closed, hollow articles may be supported by internal air pressure.

The cost of holding metals at a given constant temperature is made up of the heat losses of the furnace due to radiation and the like, the burden on the heat treating equipment, and, in the case of long heat treatments, the cost of holding the material itself in process. Heat treatments of long duration involve interest charges on the material itself, and also certain losses or difficulties resulting from interference with precise scheduling of manufacturing operations. It may be pointed out that the energy consumed or given off as a result of changes taking place within alloys during heat treatment is very slight in comparison with other factors of heat treatment cost.

Cooling—In the case of pure metals or single phase alloys in the form of articles of simple shape, which are usually heat treated primarily for the purpose of softening after cold working, rate of cooling is likely to be quite unimportant and therefore determined largely by convenience. The rate of cooling after the annealing of copper and alpha brass, for example, has little effect on the properties of the material, although the specific manner of cooling may have considerable effect on the surface of the material. It is necessary in each case, however, to consider whether a metal is really pure from the standpoint of heat treatment effects. Some commercially pure metals contain sufficient quantities of certain impurities to produce appreciable effects during cooling. It is becoming recognized, for example, that very small amounts of carbon, oxygen, nitrogen, and perhaps phosphorus may cause substantial changes in the properties of iron at temperatures below the critical range.

When the constitution of the material being heat treated is different at the maximum temperature of heat treatment from the constitution stable at low temperatures, rate of cooling is of great importance in determining the result of the heat treatment. Very slow cooling permits full development of the constitution stable at low temperatures. Rapid cooling may preserve in an unstable condition the structure which was produced at the high temperature, as in the quenching of austenitic steels and duralumin. Frequently, as in the case of plain carbon steels, the most rapid cooling possible will not preserve the high-temperature structure.*

Iron-carbon alloys cooled from above the critical range with sufficient slowness to permit the full development of low temperature structural equilibrium would consist either of ferrite and graphite or ferrite and spheroidized carbides. The intermediate structures obtained in the hardening, normalizing, and annealing of steel thus result from intermediate and controlled rates of cooling. Not only the average rate of cooling, but also the rate at each stage of the cooling operation is important.

Heat Application—Heat is imparted to metal objects by the usual processes of radiation and conduction. At high temperatures, radiation is a very important factor in the transfer of heat. In furnaces operating below approximately 1000°F., positive circulation of the furnace atmosphere is desirable to promote rapidity and

*It has been shown by Mathews that, in certain steels at least, the amount of austenite retained is greater after moderately rapid cooling, as in oil, than after a more rapid cooling, as in water. This is presumably because the internal stresses set up by water quenching help to initiate the change from gamma to alpha iron.

uniformity of heating. Heat may also be developed within the metal by the passage of electric current, led into the metal by means of contacts, or generated by induction. Means employed in heat treating include furnaces fired with oil, gas, coke, or coal; furnaces heated by electrical resistors of both metallic and nonmetallic types; liquid baths of lead, salt, or oil in which the objects to be heated are immersed; and containers into which steam is introduced.

Electrical Resistance Heating—The heating of metals by the direct passage of electric current through the work itself is quite limited in practical operation for obvious reasons. If a uniform temperature is desired, the metal object must be of uniform cross section. Steel tubing has been heated for hardening by applying contacts at the ends of each tube and passing current through the tube until the desired temperature is reached. The passing of the tube through the Ac₁ point is indicated by the discontinuity in thermal expansion. Resistance heating has been used in heating bar stock for forging, in heating rivets, and in the sintering of tungsten briquettes. In certain cases where a nonuniform distribution of temperature is desired, resistance heating may be applied to an article of nonuniform cross section (for example, in the heating of ends of valve stems for hardening).

Temperature Gradients in Heating—In resistance heating, the inside of the metal is normally hotter than the outside surface. Hence, the estimation of temperature by the color of the piece, by radiation or optical pyrometers, or by thermocouples placed outside the piece is apt to give low results.

In other methods the heat is introduced into the metal through the surface, and as long as the temperature is rising, the surface is hotter than the interior. Allowance must again be made for this difference, and in practice it is recognized that a certain period of time, increasing with the weight of the section, is required for the penetration of heat throughout the entire cross section of the piece. Heavy sections therefore lag in coming up to temperature.

Limitations on Rate of Heating—With resistance heating the rate of heating is limited only by the current available. With externally applied heat the rate of heating is limited by the thermal conductivity of the metal. If it is assumed that the surface of the object to be heated is maintained at the maximum permissible temperature, as, for example, by immersion of a small object in a large bath of lead, the time required to saturate the object is determined by the heat capacity at the desired temperature and by the heat conductivity of the metal under the temperature gradients existing.

Fuel Fired Furnaces—Any temperature employed in the heat treatment of the common metals can be readily attained in fuel fired furnaces of either the direct fired or muffle type. Furnace parts, including muffles, made of heat resisting alloys can be used up to about 1800-2000°F., but may be attacked by fuels of high sulphur content. Refractories are satisfactory up to considerably higher temperatures for hearth, walls and muffles. Conveying mechanism, and rails, which must be made of metals, are at present limited to furnaces operating under about 2000°F., unless these parts are artificially cooled or are so placed and operated that they do not attain the full temperature.

Electric Furnaces—Electric furnaces heated by metallic resistors of the nickel-chromium or nickel-iron-chromium types are limited in working temperature to about 1800-2200°F., depending on the type of work and the permissible cost of resistor replacement. Platinum-wound furnaces may be used up to about 2700-2900°F., and resistors of molybdenum or tungsten operated in hydrogen provide furnace temperatures up to at least 3100°F., limited by the refractory rather than the resistor. Carbon (or graphite), in solid or granular form, can be used as resistor material up to very high temperatures, but is attacked by both oxygen and hydrogen. Industrial electric furnaces operating above the temperature range for nickel-chromium alloy resistors are at present usually heated by synthetic resistor bars consisting largely of silicon carbide, or by recently developed alloy resistors of the iron-chromium-aluminum type.

Furnace Atmospheres—One of the problems in the heat treatment of steel and some other metals is concerned with oxidation or the formation of scale,^{6, 7} and much is said regarding so-called "neutral" atmospheres. It is to be noted that there are

⁶C. Upthegrove and D. W. Murphy, Scaling of Steel at Heat Treating Temperatures, Trans., A.S.S.T., 1933, v. 21, p. 73.

⁷W. E. Jominy and D. W. Murphy, Scaling of Steel at Forging Temperatures, Trans., A.S.S.T., 1930, v. 18, p. 19-57.

no truly neutral atmospheres except the rare gases. These have actually been employed in special cases, but are too expensive for ordinary work. Other furnace atmospheres are to be regarded as chemically active, the kind and extent of the action depending on the composition of the metal, the composition of the atmosphere, and the temperature.

The most common atmospheres are those resulting from the partial or complete combustion of coal, oil, or gas. The possible ingredients of such atmospheres include oxygen, nitrogen, carbon dioxide, water vapor, carbon monoxide, hydrogen, hydrocarbons, sulphur dioxide, and (rarely) hydrogen sulphide. Of these, oxygen, carbon dioxide, water vapor, and sulphur dioxide are oxidizing. Hydrogen is reducing. Carbon monoxide may be reducing or oxidizing, but toward iron its effect is predominantly reducing. Nitrogen is substantially neutral toward most of the common metals at heat treating temperatures, but reacts with magnesium above about 750°F. to form a nitride. Sulphur dioxide and hydrogen sulphide may impart sulphur to steel.^{8,9} Hydrocarbons and carbon monoxide may carburize, while the oxidizing gases, and also hydrogen, may decarburize.¹⁰

The most common kind of action with which we have to deal is oxidation. All of the common metals are oxidized readily at heat treating temperatures. The heat resisting alloys depend for their protection on the formation of a thin scale of a kind that prevents or retards further oxidation.¹¹ The elements commonly used to produce these protective films are aluminum, chromium, and silicon. It is interesting to note that all three have in themselves a very strong affinity for oxygen.

Reactions (2) and (3) are reversible. A mixture of CO and CO₂ will oxidize iron at elevated temperatures if relatively rich in CO₂, but will reduce iron oxide if relatively rich in CO. Likewise, a mixture of H₂ and water vapor is oxidizing if high in water vapor, but reducing if high in hydrogen.

The compositions of gas mixtures which are neutral, with respect to oxidation and reduction, vary with temperature.^{12,13} For example, a mixture containing 65% hydrogen and 35% water vapor will reduce iron oxide at 1600°F., but will scale iron at 1000°F. A piece of iron could thus be heated in such an atmosphere indefinitely at 1600°F. without scaling, but would form a thin scale on cooling to room temperature in the same atmosphere. This atmosphere will not prevent the formation of scale on high chromium steels even at a high temperature, because slight traces of water vapor will oxidize chromium. The scale will no longer, however, have the normal brown appearance (due to iron oxide) but a dark green color characteristic of chromic oxide.¹⁴

The gases discussed above (resulting from combustion) also include most of those which are sometimes injected into furnaces or heat treating containers to produce a definite desired atmosphere. Ammonia is of special interest as a fairly cheap source, by decomposition, of a mixture of hydrogen and nitrogen.

Because a high percentage of commercial heat treating operations are applied to steel, the attainment of a furnace atmosphere which is nonoxidizing toward steel is of special interest. The complete combustion of the fuel produces carbon dioxide or water vapor or mixtures of these gases. Both of these gases are oxidizing toward iron. A nonoxidizing atmosphere resulting directly from the combustion of a fuel must therefore represent incomplete combustion, so that enough reducing gases such

as carbon monoxide and hydrogen are present to prevent oxidation. The fact that combustion must be incomplete imposes a limit on the flame temperature, depending on the heating value of the fuel and the temperature of the air (or oxygen) used for combustion. When a muffle or other device is used to separate the work from the products of combustion, the fuel may be completely burned outside of the container and any desired atmosphere may be maintained inside, using a separate source of gas if necessary. Commonly, an attempt is made to partly burn the fuel inside of the muffle and to complete the combustion outside of the muffle.

A considerable amount of heat treatment is being done in retorts, of both batch and continuous types, where the products of combustion do not come into contact with the work and where the atmosphere in the retort is controlled to produce definite results. In this way steel may be nitrided and carburized, and high carbon steels may be hardened without oxidation, stain, carburizing, or decarburizing.

The nature of the scale formed on steel may be of as great importance as its thickness, since a thick scale can often be removed more easily than a light scale. For example, nickel steels and stainless steels form a lighter scale under the same conditions than straight carbon steel but are apt to be more difficult to clean.

Steam Tanks—Steam may be used conveniently for the attainment of temperatures up to about 300°F. and is used especially in the precipitation heat treating of aluminum alloys.¹³ The condensation of the steam in the cold parts of the charge automatically results in rapid and uniform heating and temperature can be closely controlled by the regulation of pressure.

Liquid Baths—Liquid baths¹⁴ are available for heat treatment up to about 2300°F., those commonly employed covering approximately the following ranges:

Water	Up to 212°F.
Oil	Up to 500°F.
Salt	300-2300°F.
Lead	650-1700°F.

The temperature range given for salt baths covers several types of salt, no one type being suitable for the entire range. Liquid baths exclude air and furnace atmospheres from the work and are therefore protective unless the bath material itself has some undesirable action on the metal. Liquid baths also have the advantage of providing rapid heating, and great uniformity of temperature can be attained when the bath itself is sufficiently circulated and the work is left in the bath for a sufficient time. On the other hand, the very rapidity of heating, especially in the case of the lead bath, is especially useful for localized heating when this effect is desired.

Temperature Measurement—Accurate temperature measurement is vital in heat treatment. Usually it is best to measure accurately the temperature of the work itself, and the importance of properly placing thermocouples for this purpose is discussed in the article on Pyrometry in this Handbook. Often in the heat treatment of many articles of the same material (form and size) the operation is regulated by measuring the temperature, not of the articles themselves, but of some point in the furnace whose temperature bears a reasonably fixed relation to that of the work, when the work is in the furnace for the same time or traveling through the furnace at the same rate. In continuous furnaces, especially, this may be the most convenient method of control. There are obvious uncertainties in this method, however, and wherever possible it is preferable to determine the temperature of the work itself.

Quenching—Heat can be removed from a solid object only by dissipation from its surface. The rate of cooling of a given object from a given temperature depends therefore on the surface temperature of the object during the cooling process. The shortest possible time of cooling is obtained when the surface is maintained substantially at the temperature of the cooling medium; the time then depends on the thermal conductivity of the material.

The decreased surface temperature necessary to promote rapid cooling may be obtained by removing the object from sources of radiant heat, so that it can radiate its own heat freely without receiving return radiation, and by bringing into contact

¹³See "Heat Treatment of Wrought Aluminum Alloys of High Strength" in this Handbook.

¹⁴See "Lead Baths," "Salt Baths," and "Cyaniding," in this Handbook.

with the surface of the object some cooler material, which may be gaseous, liquid, or solid. A fine wire or thin sheet will cool rapidly by radiation alone, especially in the high temperature range. Observe, for example, the rapid cooling of the filament in a vacuum lamp when the current is turned off. Heat dissipation by radiation is slow at low temperatures, however, and even at high temperatures is too slow to result in very rapid cooling of any but very thin sections.

The application of a cooler material to the surface of an object to promote rapid cooling is called quenching. This may be by means of a current of some gas, such as air; a spray or jet of liquid, such as water; immersion in a liquid such as water; application of a cold solid, such as cooling (quenching) between plates or in a press; or by combinations of these means.

It is seldom that the cooling medium can be applied to a clean surface of the metal itself, because this surface is usually covered with some sort of scale or oxide film. These nonmetallic coatings have less thermal conductivity than the metals, so they retard cooling. Heating in such a way that oxidation is prevented or minimized is therefore conducive to rapid cooling on quenching.

To produce the most rapid quenching, the cooling medium must be kept in contact with the surface of the metal, and that portion of the cooling medium immediately in contact with this surface must be kept cool. With gases, such as air, there is no difficulty in maintaining close contact. The heat capacity and heat conductivity of air are quite low, however, so very rapid and uniform circulation and large volumes of air are required to keep the air immediately in contact with the surface of the metal cool. Gases are not, therefore, generally suitable or economical for rapid quenching.

Liquids have much higher heat capacities than gases, the specific heat of water in particular being substantially the highest known. The problem of maintaining contact between a liquid quenching medium and the object to be quenched is one of keeping gases from adhering to the surface of the object. These gases may be carried into the quenching medium by the object itself (adsorbed on the surface or trapped in pockets) or may come from the quenching medium by liberation of dissolved gas, such as air in water, or by vaporization of the liquid itself. Gases arising from these sources and adhering to the surface of the object insulate the object from the liquid and thus retard cooling. Circulation of the liquid against the surface helps to remove gases, and also tends to prevent the liberation of gases or vapors from the liquid, by preventing the overheating of the liquid in contact with the surface. By boiling, water can be substantially freed from dissolved air before using it for quenching.

When it is desired to cool certain portions of an object more slowly than the object as a whole, such as holes and keyways, in steel to be hardened, these portions may be shielded from the full action of the cooling medium by the application of clay, asbestos, and sodium silicate, or other insulating material.

The effect of a quenching medium on the properties of a metal depends on the rate of cooling produced. There is no evidence of any magic effect due to the composition of certain local waters, curious aqueous solutions, or odd mixtures of oils which have been used or proposed, except insofar as cooling rate is affected.

It is to be noted, however, that the *average* rate of cooling from the quenching temperature to that of the quenching medium is not a sufficient indication of the effect on the metal. The rate of cooling at all temperatures on the way down must be considered. For example, a certain object made of an alloy tool steel may be found to crack when quenched in cold water for hardening. Slower cooling is indicated, and the object may be successfully quenched in a certain oil without cracking. Equally slow cooling through the higher temperature range may be obtained by quenching in boiling water, but the object may be found to crack. This is because the cooling rate is too rapid at lower temperatures—say from 700-300°F.

The cooling rates imparted by various quenching media to steel, in particular, have been carefully studied.^{17, 18} Detailed data on this and other phases of the art

¹⁷H. J. French and T. E. Hamill, *Hot Aqueous Solutions for the Quenching of Steel*, Trans., A.S.S.T., 1929, v. 16, p. 711.

¹⁸H. J. French and O. Z. Klopsch, *Quenching Diagrams for Carbon Steels in Relation to Some Quenching Media for Heat Treatment*, Trans., A.S.S.T., 1924, v. 6, p. 251.

of quenching will be included in one or more additional articles in the Handbook.

When the ratio of the surface of an object to its volume is large, as in wire and thin sheet, extremely rapid cooling can be obtained by a quenching method which rapidly cools the surface, such as a jet of cold water of ample volume and under high pressure. With heavier sections, however, cooling rate is limited by the rate of conduction of heat from the interior to the surface. Hence, it becomes impossible by any method to rapidly cool the center of a large section of steel. If the composition of the steel is such that rapid cooling is necessary for full hardening, it is then impossible to cool the center rapidly enough for such hardening. This is called the "mass effect."¹⁹

Different quenching media may be used in sequence to produce different rates of cooling. For example, a tool may be air cooled for a short time before quenching in water, to reduce distortion and strains, or a crankshaft of alloy steel may be quenched in water for a measured time and then removed and allowed to cool in air, or transferred to oil, to prevent cracking.

¹⁹See "Mass Influence in Heat Treatment" in this Handbook.

Recrystallization

By R. F. Mehl*

Metals which have been strained by cold working are not stable, but tend to revert to a strain-free state. This article will consider the processes, of which recrystallization is the chief, by which the effects of cold work may be relieved. In order to understand these processes, it will first be necessary to consider the effect of cold work on the nature of metals.

The Nature of Cold Worked Metals—Cold work consists in the plastic deformation of a metal at such temperatures and at such rates that no recrystallization occurs during the deformation process; under such conditions the metal is strain hardened. The compression of iron at room temperature, for example, is cold work; but the compression of iron at higher temperatures in the absence of recrystallization is also cold work. Only when such temperatures are reached that recrystallization (which leads to softening) occurs during the working process, can the term hot work be properly employed; in general, these temperatures are high in metals melting at high temperatures and low in metals melting at low temperatures—occasionally as low as room temperature or below. Since permanent plastic deformation is required, it will be obvious that the deformation must be beyond the yield point.

Such deformation produces fundamental structural changes in the metal. At low degrees of deformation, slip lines appear in those grains in which the slip planes are most favorably oriented for yielding under the resolved shear stress; in metals which readily form mechanical twins, like zinc at ordinary temperatures or iron at low temperatures, twin bands also appear; as the degree of deformation becomes greater, slip lines appear in an increasing number of grains, the grains tend to rotate, the crystal planes to become curved, and the grains to become sensibly elongated in the direction of flow. It is a result of the fact that the directions in the crystal grain by which flow can take place during deformation are determined by lattice symmetry and are therefore not random, that cold (and hot) deformation is accompanied by the generation of preferred orientations, which may be described in crystallographic terms, accompanied by corresponding directional properties. This deformation is accompanied by an increase in the strength properties: Hardness, yield point or strength, tensile strength; and a decrease in the ductility properties: Elongation to fracture, reduction of area at fracture, drawing capacity, impact strength; it is accompanied also by a slight decrease in density, a slight decrease in electrical conductivity, and a decrease in maximum permeability, and by an increase in electrode potential, an increase in coercive force, a slight increase in the coefficient of thermal expansion, and a slight increase in compressibility.

The atoms in an annealed metal are in a continuous state of thermal vibration about mean positions which are symmetrically disposed on a space lattice; apart from relatively minor imperfections, this is a geometrically perfect arrangement. The perfection of this arrangement, however, is grossly altered by deformation: The lattice planes become curved and twisted, atoms no longer have precision mean positions on a space lattice but are distorted to positions less symmetrically disposed, with resultant distortion of atom shapes and energy distribution and increase in the internal energy of the metal.

The nonhomogeneous character of cold deformation creates a pattern of internal strains. In commercial forming operations, the friction of rolls or of dies, or the complexities introduced by multiple types of deformation or by heat treatment, create internal "macroscopic stresses," (Heyn stresses). These macroscopic stresses are characterized by a gross distribution in such a way that one section of a piece may be in tension while another is in compression; thus, for example, the center of a cold drawn copper wire is in compression while the outside is in tension. Furthermore, a pattern of stresses on a fine scale, "microscopic stresses," characterized by minute regions in which tensile (and compression) stresses occur, also are formed as a result of slip on atom planes, of the bending of slip planes, of slip on intersecting slip planes, and of the impedance to normal slip at grain boundaries. Such a pattern of stresses will obviously be characterized by points of unusually high energy peaks, which are the points of least stability in the cold worked metal

*Director, Metals Research Laboratory and Head, Department of Metallurgy, Carnegie Institute of Technology, Pittsburgh.

where processes relieving the effects of cold deformation will originate. The greater the amount of cold deformation the greater will be the number of such peaks.

The heating of cold worked metals results in a softening and accordingly a renewed ability to suffer cold work. This heating also relieves both microscopic and macroscopic internal stresses, either of which may be harmful in special cases though generally cold worked materials find widespread and wholly satisfactory applications. Macroscopic stresses can measurably decrease the fatigue strength of materials, can be conducive to failure in stress corrosion as in season cracking, and can lead to the yielding of structural members at loads below the normal yield strength. Any softening process which will obviate these effects is obviously important practically; it will be seen that both the process of recovery and that of recrystallization will perform this task.

The Effect of Annealing on Cold Worked Metals—The changes in properties which follow upon annealing are in the direction of the restoration of the properties obtaining before cold deformation. But the ways in which the various properties change on annealing are not simple.

Fig. 1—Schematic representation of recovery, recrystallization, and grain growth (Adapted from Sachs).

Three types of mutually distinguishable processes occur on annealing a cold worked metal. These are: (1) Recovery, (2) recrystallization, and (3) grain growth, as illustrated in Fig. 1. Recovery is a change in the properties, particularly those determined by the state of internal strain, of a cold worked metal at low annealing temperatures that is unaccompanied by any detectable change in the microstructure of the cold worked metal. Recrystallization, occurring at higher temperatures, is a process of the formation and growth of new unstrained grains, supplanting entirely the cold worked structure. Grain growth, occurring in completely recrystallized metals, is merely a continued growth of recrystallized grains.

These three processes are all dependent upon time—they are not instantaneous. The rate at which each operates increases with increasing temperature following an exponential law. When the temperature to which a cold worked metal is subjected is sufficiently high, these processes operate with such rapidity as to appear to be instantaneous, but at lower temperatures the time dependence is readily detected. The rates, however, vary widely from metal to metal and are greatly dependent on composition, purity, grain size of the sample before deformation, and the amount of deformation. Generally speaking, metals with low melting points exhibit high rates at low temperatures, as in the case of tin. Furthermore,

the three processes sometimes overlap and are difficult to distinguish, while in other cases they can be clearly separated. The accompanying changes in properties are not always parallel, that is, the properties do not change concomitantly (Fig. 5), and this fact often permits the production of unusual property combinations.

Recovery, recrystallization, and grain growth are all processes leading to softening. It is conventional to study these by heating cold worked samples to a series of increasingly elevated temperatures and holding for a certain time period, usually between 15 min. and 2 hr., and subsequently measuring the properties at room temperature.

The selection of a constant time period of annealing eliminates time as a variable, and the results must be viewed with this limitation. In a narrow temperature range the change in properties is rapid, as shown in Fig. 2 for copper of various degrees of purity, but this range may readily be displaced to lower temperatures by increasing the time of annealing (Fig. 3); in a rough way, doubling the annealing time lowers the softening temperature by 10°C. The temperature of rapid softening is also decreased by an increasing degree of cold work (Fig. 4).

These curves of softening do not distinguish the three processes described above with absolute certainty. Of the three processes, recovery should be considered first since it is the process which occurs first on heating.

Fig. 2—Effect of annealing on tensile properties and grain size of tough pitch lake, tough pitch electrolytic, phosphorized (0.02% P), and oxygen free high conductivity copper. Wires cold drawn to 62.5% reduction in area and annealed one hour (Pratt).

Recovery—The elongation of single crystals is characterized by a steadily rising stress-strain curve. If the load is removed and immediately reapplied, the stress continues from the point of interruption; if, however, time elapses between release and reapplication of load, or if the piece is slightly heated, the stress begins at a low value, that is, strain hardening has been lost, though no recrystallization has taken place. This is recovery, sometimes termed crystal recovery. The process is most striking in single crystals but occurs also in aggregates.

The effect of recovery in iron on several physical properties is shown in Fig. 5. The Brinell hardness decreases rapidly upon recrystallization, and only a very slight

Fig. 3—Influence of annealing time on softening of copper wire, reduced 93% by cold drawing to dia. of 0.26 mm. (Alkins and Cartwright).

Fig. 4—Softening temperature of cold rolled high purity copper in dependence upon per cent reduction of thickness (Köster).

decrease as a result of recovery occurs before this, but the thermoelectromotive force and the electrical conductivity decrease at much lower temperatures, and the change in these is complete before there is any detectable change in grain structure, any recrystallization. This behavior, then, illustrates a change which occurs on heating cold worked metals without recrystallization; it will be seen that the several properties do not change in a parallel way.

Recovery is especially marked in the relief of internal stresses, as shown by the curve for "spring back" in Fig. 5. The tendency to season-crack in brass, the magnitude of macroscopic stresses, and the general tendency to crack on treatment are greatly decreased by annealing to induce recovery without recrystallization; such stresses in cold worked steel can be largely eliminated by annealing at 850°F., at which temperature steel does not recrystallize. Complete stress relief can be more completely attained by annealing to higher temperatures, and this is the usual commercial practice.

The process of recovery in metals is doubtless widespread, though experimental studies have not been sufficiently extensive to say when recovery may be separated from recrystallization and when these two processes overlap. In the latter case, distinction cannot be made. In Fe, Ni, Pd, and Pt, recovery may be readily distinguished from recrystallization, for the changes in properties on heating are not parallel (Fig. 5), but in Cu, Ag, and Au, the properties change more nearly simultaneously upon annealing; whatever may be the underlying cause of these differing behaviors, it may be seen that the type of space lattice is not important, but that the position in the periodic table is.

The causes for recovery are not clear. Recovery is doubtless a change in the internal stresses in worked metals, affecting primarily the elastic properties, and also the electrical, magnetic, and miscellaneous properties like velocity of solution in acids, but having relatively little effect on the strength and ductility properties. This stress removal may be associated with the straightening of bent slip planes, and perhaps with the healing of microscopic cracks adjacent to points of severe curvature of slip planes; it cannot, however, be pictured as a complete relief of stress, but only as a partial relief of some special sorts of stress, for a metal which has recovered does not lose its capacity to recrystallize, and in some cases an entirely undiminished capacity for recrystallization has been demonstrated. The reasons for strain hardening in cold working are not well understood, and until the cold worked condition itself can be more adequately described, it is unlikely that recovery and the types of stresses causing recovery and recrystallization can be more clearly understood.

Recrystallization—On heating a cold worked metal to a sufficiently high temperature, or for a sufficiently long time at a somewhat lower temperature, new grains appear and grow, until ultimately a new grain structure has completely replaced the old. This is recrystallization. The changes in properties which accompany recrystallization are in the direction of the restoration of the properties characteristic of the metal before cold deformation, though these properties may not be exactly reproduced, for the final grain size may be different from the initial. The softening temperatures illustrated in Fig. 2, as shown by the rapid increase in elongation and decrease in strength, are temperatures at which recrystallization occurs, and generally such property changes can be safely taken as evidence for recrystallization, but when the material has partially recovered before recrystallizing, the changes in strength properties do not sharply define the beginning of recrystallization, and when grain growth after recrystallization is pronounced the

Fig. 5—Recovery and recrystallization in iron. Annealing time one hour; cold rolling 95-98%. "Spring back" is the increase in dia. of a roll of strip after removing from mandrel about which it had been held (Adapted from Tammann).

strength properties continue to change after the completion of recrystallization and thus do not sharply define the completion of recrystallization; in such cases microscopic studies are required to define the beginning and the ending of recrystallization though frequently X-ray diffraction methods are much superior.

The complete removal of the effects of cold work and the possibilities of controlling grain size, and thus particularly the behavior of the material toward further working, make recrystallization a process of immense practical importance. Unusually large grains are often highly undesirable, for they lead to an unattractive rough appearance of drawn objects (for example, the familiar "orange peel" effect), and to tears in large worked sections. It is therefore of the greatest importance to know what factors govern the temperatures and times of recrystallization and what factors govern the final grain size.

The process of recrystallization is one of the continuous formation of nuclei of new crystals and the growth of these nuclei until the system is wholly constituted of the new grain structure. The rate of formation of nuclei and the rate of growth of these nuclei are thus the basic factors determining the rate of recrystallization, and it is necessary to inquire how these may vary with temperature, with time, with initial grain size, with degree of deformation, and with composition and purity.

Recrystallization is thus not an instantaneous process but one with a clearly apparent time dependence. It is in this sense entirely similar to the formation of pearlite from austenite, giving rate curves of a completely analogous form. Most recrystallization data, however, have been obtained by employing short and fixed annealing times, as stated above, and thus give no clue to this time dependence.

The new nuclei appear to prefer to form at grain boundaries, slip lines, deformation markings of various sorts, and twinning planes, as may be seen in slightly deformed samples, though this is probably also true in heavily deformed samples. Recrystallization can thus most conveniently be detected metallographically, but the sharpening of X-ray diffraction spots and the appearance of new sharp spots can be and has frequently been used as a trustworthy criterion. The mechanical properties are not always trustworthy, as stated above.

Apart from composition and purity four factors determine the grain size after recrystallization: (1) The amount of cold deformation, (2) the temperature to which the cold worked metal is heated, (3) the time for which the metal is held at this temperature, and (4) the original grain size.

Several fundamental laws of recrystallization are now well recognized: (1) Recrystallization occurs at a higher temperature the smaller the degree of deformation or, more accurately, the smaller the degree of strain hardening. (2) Increasing time of annealing displaces recrystallization to a lower temperature. (3) The final grain size is chiefly dependent upon the degree of deformation and to a lesser degree on the annealing temperature; the final grain size is the larger the smaller the degree of deformation. (4) The larger the original grain size the greater the amount of cold deformation to give equivalent recrystallization temperatures and times. In addition to these major factors, it should be noted that (a) the rate of heating to the recrystallization temperature is a further variable, and (b) the amounts of cold work to give equivalent strain hardening vary with the temperature at which deformation is performed.

The first law may be illustrated by a diagram in which the beginning of recrystallization is plotted against annealing temperature for cold worked iron (Fig. 6). Here it may be seen that recrystallization does not occur below 460°C., and that the temperature of beginning recrystallization increases with decreasing deformation

Fig. 6—Curve of initial recrystallization of low carbon steel in dependence upon temperature and degree of deformation at temperature (Hanemann).

Fig. 7—Grain size developed at 950°C. in low carbon steel in dependence upon degree of deformation (Hanemann).

until the A_1 temperature is encountered. This diagram, obtained for deformation at the temperature of recrystallization, differs from a diagram for deformation at room temperature and recrystallization at the designated temperature only in degree—the general form is the same, as indeed it is for all metals and alloys. Therefore, for degrees of deformation and annealing temperature to the left of and below the curve of beginning recrystallization, no recrystallization occurs, no change in the grain structure can be detected; in this range recovery occurs.

The exact position of such a curve will vary with a number of factors, with the type of deformation, with the original grain size, and with purity. Even slight differences in purity exert a wholly disproportionate effect. Data on recrystallization are given elsewhere in this Handbook; see, for example, the article on the Effect of Cold Work on the Properties of Iron, and other articles on the properties of various metals and alloys. It is ordinarily difficult to determine the applicability of published data to a given material, for frequently important variable factors have been disregarded, especially in the older publications.

The grain size developed on heating samples which have been deformed to increasing degrees is especially instructive (Fig. 7). Here we see that a deformation of approximately 7% is required before any change in grain size occurs; this degree of deformation, at which grains suddenly grow to a large size, is known as the critical deformation.

The formation of large grains on recrystallization at the minimum deformation is probably caused by the occurrence of a minimum of recrystallization nuclei; at degrees of deformation below this the number of recrystallization nuclei becomes disappearingly small. With increasing degrees of deformation, an increasing number of points of high stress (high energy) are present, leading on recrystallization to a greater number of nuclei and finally to a greater number of grains and thus to a continually smaller grain size.

Fig. 8—Influence of degree of deformation and time of annealing upon recrystallization temperature of copper deformed by elongation in tension (Adapted from Sachs).

The influence of degree of deformation on the recrystallization temperature and time is illustrated in Fig. 8. This figure shows that for a constant annealing temperature shorter times are required for recrystallization at higher degrees of deformation, and shows also that with increasing temperatures lower degrees of deformation and shorter times are required for recrystallization. Such generalizations are applicable when the type of deformation is simple, as, for example, increasing amounts of compression, but when several types are superimposed, or when reversed deformation occurs—alternate compression and elongation, bending and unbending—the recrystallization tendency is decreased even though reversed deformation may continue to work harden. The reason for this is not clear.

The effect of original grain size on recrystallization can readily be understood. The amount of strain hardening which a given amount of compression, elongation, or torsion introduces into a metal increases as the grain size decreases. When, in a given metal at a single temperature, equivalent amounts of strain hardening are introduced, requiring large amounts of deformation for large grained metals and small amounts of deformation for small grained metals, the recrystallization behaviors are apparently identical.

The relationships between degree of deformation, annealing temperature, and resultant grain size have frequently been assembled into a three dimensional chart, of which Fig. 6 and 7 are sections. Such a diagram for iron is given in the article on the Effect of Cold Work on the Properties of Iron in this Handbook. Charts of this sort are commonly derived from data obtained using constant (and short) annealing times, and do not show the time variable; furthermore, the factor of original grain size is not represented. A five dimensional chart would be required to show all of these relationships. This limitation of three dimensional diagrams, the occasionally extreme effects of minor amounts of impurities, and the complications introduced by the complexities of industrial forming processes with resultant complexities in internal stress distribution, render such charts of little direct practical use. They should be used only to indicate the recrystallization behavior of a material in a qualitative way.

Recrystallized metals, like cold worked metals, can exhibit preferred orientations and directional properties, though they may not be identical with those which characterized the cold worked metal before recrystallization. Relatively little is known concerning the inheritance of preferred orientations during recrystallization, and no generalizations can be made.

Impurities in solid solution exert a pronounced effect upon recrystallization temperatures. The relatively minor variations in composition in the several varieties of copper represented in Fig. 2 may be seen to have caused a difference of 100°C. in the softening temperatures, and more extreme cases have been noted. Increasing concentrations in solid solution become increasingly less effective until, in a completely isomorphous system a maximum recrystallization temperature is reached at an intermediate composition, which may be several hundred degrees Centigrade above those of the component metals. It has frequently been stated that impurities which do not form solid solutions have little effect on softening and recrystallization temperatures; this generalization is somewhat doubtful, for at least in the case of aluminum alloys such impurities are employed to raise the temperatures required for recrystallization, and when present in a sufficiently fine state of subdivision are more powerful in this respect than elements in solid solution.

Grain Growth—Fig. 2 shows softening and recrystallization to have been completed at 400°C., but shows also an increasing grain size on heating beyond this temperature. This growth of grains in an essentially completely recrystallized and strain free structure is known as grain growth. It proceeds in an endeavor to decrease the grain boundary area and thus the internal energy. Grain growth proceeds by the absorption of grains, in the usual case of smaller by larger grains, and doubtless accompanies and overlaps recrystallization at least to some degree. It is especially noticeable following the recrystallization of severely deformed aggregates, for the grain size after recrystallization in this case is small and grain growth is readily noted, whereas in samples recrystallized after slight deformation the grain size is large and the subsequent grain growth is minor. Slow heating favors the growth of large grains, which in some cases may become very large.

Impurities in solid solution have a minor effect on grain growth, but undissolved impurities exert a pronounced effect. With very pure substances grain growth proceeds steadily, with the average grain size increasing with increasing annealing temperature (Fig. 2). But if undissolved impurities, such as ThO₂ in tungsten, iron in aluminum, lead in zinc, are present in the proper amount, the grain size is then small at low temperatures and suddenly increases in a narrow temperature range forming unusually large crystals; when the amounts are larger grain growth may be entirely obviated. Thus immiscible impurities may be used either to suppress grain growth at relatively low temperatures or to create unusually large grains at higher temperatures.

Bibliography—The bibliography on recrystallization is extraordinarily voluminous, and it is unnecessary to reproduce all of it here and useless to reproduce only selected references. The most complete summaries are those given by G. Sachs, "Praktische Metallkunde, v. II, Spanlose Formung", Julius Springer, Berlin, 1934; and E. Schmid and W. Boas, "Kristallplastizität", Julius Springer, Berlin, 1935. Sachs gives a complete summary except for iron and steel, while Schmid and Boas stress the scientific aspects of the subject. Data on the recrystallization of iron and steel may be found in P. Oberhoffer, W. Eilender, H. Esser, "Das Technische Eisen", Julius Springer, Berlin, 1936; and E. Houdremont, "Sonderstahlkunde", Julius Springer, Berlin, 1935. The material in the present paper has been drawn largely from these sources. An extensive bibliography on the recrystallization of iron and steel has been given by H. F. Kaiser and H. F. Taylor: "The Effect of Cold Deformation on the Recrystallization Properties of Armco Iron," American Society for Metals, preprint, 1938 fall meeting.

The Relation of Design to Heat Treatment*

Design bears in many ways upon the serviceability of a tool or machine part, and unsatisfactory performance may frequently be traced directly to faulty design. This report is concerned only with design as it affects the heat treating operation—and through the heat treatment, the serviceability of the finished parts. It is the purpose of this report to bring about a better mutual understanding between the designer and the steel treater so that faulty design which may cause cracking, or distorting, during heat treating can be avoided.

The fundamental principles of good design from a heat treatment standpoint are quite simple. Heat treated steel has a certain strength depending upon the analysis of the steel, the quality of the metal, and the heat treatment which it has received.

When subjected to a combination of forces beyond its ultimate strength, the steel cracks or fails. There are two types of force combining to break the steel: 1. The internal strains set up during fabrication and heat treatment of the part; 2. The external forces of service. Sometimes the internal strains alone exceed the strength of the metal and the part cracks in hardening. Again, the internal strains may equal 90% or more of the total strength, in which case failure will develop in service under relatively light loads. It, therefore, appears that the useful strength of a part decreases in proportion as the internal strains increase.

Internal strains arise from many causes, but the most serious, by far, are those developed during quenching, by reason of differential cooling. This differential cooling (or more accurately "temperature gradient"), is largely a function of the size and shape of the piece being quenched, in other words, the design. Here, then, is the relation of design to heat treatment, and the basic principle of successful design is to plan shapes which will keep the temperature gradient throughout a piece at a minimum during quenching.

Temperature gradient is the rate of variation in the temperature of metal over a given unit distance.

Fig. 1—This cube illustrates what is meant by temperature gradient.

Fig. 2—When quenched, the point of this tapered pin will cool faster than the heavier section.

Fig. 1 may be taken to represent a steel cube interrupted during the process of quenching. Consider the points A and B separated by a distance "d". If, at any given instant during the quench, A is 700°F. and B is 300°F. and "d" equals 1 in., the temperature gradient between these two points is 400°F. per in. If the points are only ½ in. apart, the gradient is said to be twice as steep.

Some shapes are almost impossible to harden because of the abruptness in the change of section, but a certain latitude in design is recognized when using an oil hardening or air hardening steel. All things being equal, the gradient between A and B, in Fig. 1, will be much less in oil than in water, and will be less

*Prepared for the Subcommittee on Relation of Design to Heat Treatment by Frank R. Palmer, Carpenter Steel Co. The membership of the subcommittee was as follows: A. H. d'Arcambal, Chairman; F. R. Palmer, H. J. Stagg, G. M. Eaton, W. H. Wills, A. L. Boegehold, and F. T. Quinlin.

in air than in oil. Thus, a certain design may be perfectly safe for one kind of steel, or one type of coolant, and unsafe for another.

Errors in design reach farther than merely affecting the internal strains during hardening. A sharp angle serves to greatly concentrate the stresses of service, and the design of the part may be entirely responsible for concentrating the service stresses at a point already weakened by internal strains produced during hardening. Design errors of this type are illustrated in Figs. 7, 14, 15, 23, and 24. Concentration of service stresses frequently parallels concentration of heat treating strains and is frequently caused and cured by the same combination of circumstances.

Reducing all the above to a single statement, a part is properly designed, from a standpoint of heat treatment, when the entire piece may be heated and cooled at approximately the same rate during the heat treating operation. Perfection in this regard is unattainable because, even on a sphere, the surface cools more rapidly than the interior. The designer should, however, attempt to so shape his parts that they will heat and cool as uniformly as possible. The greater the temperature difference between any two points on a given part during quenching, and the closer these two points are together, the greater will be the internal strain and, therefore, the poorer the design.

There are really not many possibilities for subdividing this main thought. Almost every failure due to improper design can be attributed directly to a violation of the fundamental principle. Some general cases may, however, be considered.

Fig. 3—This illustrates the manner in which the different positions of a piece will cool when quenched.

Fig. 4—A light section adjoining a very heavy section.

Effect of Shape on Cooling Speed—When a piece of steel is removed from the hardening furnace preparatory to quenching, it is presumably at a uniform temperature. As soon as quenching begins, the temperature is different in almost every part of the section. This difference in temperature is due to two conditions. In the first place, the heat capacity or heat storage may be greater in one part of the section than in another, due simply to the fact that there is more metal in one part than in another. This is illustrated simply by a tapered pin, as shown in Fig. 2. Obviously, the point of this pin will cool faster than the heavy section, because there is less heat to be dissipated per square inch of cooling surface.

The rate of cooling is also affected by the shape of the surface. Fig. 3 illustrates a piece which is quite uniform in cross section, but which will not cool uniformly. The protruding corners, such as A, are cooled from three sides so that the extreme corner is giving off heat from approximately seven times as great an area as it is receiving heat. An edge, such as B, is cooled from two sides and is giving off heat through three times as great an area as it is receiving heat. A point on the flat side, such as C, receives heat from one side and delivers it from the other, and the cooling area and the heating area are approximately equal.

At a re-entrant angle, such as D, heat is being supplied to the surface through three times as great an area as it is being dispelled, and this point will naturally cool last. Sharp re-entrant angles are always objectionable from the standpoint of design. It is impossible to get uniform cooling during the quench in the immediate neighborhood of a sharp angle. Vapor pockets will frequently form in the corners and produce an actual soft spot. Even if no soft spot is formed, the rate of cooling

at the point of the angle is bound to be slow, because the corner is so inaccessible to the coolant. Differential cooling thus sets up heavy internal strains at a point which is almost certain to receive concentrated stresses in service.

It will be seen from the above that it is possible for one part of a section as shown in Fig. 3 to cool many times faster than another part.

If we have a section as shown in Fig. 4, we have a combination of the conditions given in both previous illustrations. The heat capacity of the body "B" is much greater than the projection A, and we have a sharp re-entrant angle at point C. It would be practically impossible to harden such a shape in water without cracking at the sharp corner. Even oil quenching would be doubtful on a piece of these proportions, and only by cooling in air could we expect to keep the thermal gradients down to a safe point (where the design is such that there is danger of cracking, air quenching should be used). A few practical illustrations are given in Figs. 5 and 6 to illustrate the above principles.

Fig. 5 illustrates an under-cutting form-tool. It will be noticed that the cross section of this tool is made up of heavy and light sections joined together with

Figs. 5 and 6—An under-cutting form-tool showing methods of dealing with heavy and light sections. Fig. 5 shows incorrect design and Fig. 6 shows correct design.

sharp re-entrant angles. A tool of this shape would be extremely hazardous to harden either in a water hardening tool steel or a high speed steel.

A corrected design for the above tool is illustrated in Fig. 6. Holes have been drilled through the two heaviest sections, and thus the weight of the metal has been fairly well balanced throughout the cross section of the tool. The sharp angles on the cutting edge cannot be eliminated because they are a part of the form of the tool. Two suggested treatments are shown for the angle at the base of the dovetail. The best treatment is shown at A, where a generous fillet is provided. An alternative is shown at B, where the corner has been under-cut to provide a radius and still give the effect of a sharp corner. From a standpoint of quenching strains, the under-cut form at B has little to recommend it, but it does have the advantage that there is no absolutely sharp corner in which the stresses can accumulate.

Fig. 7 illustrates a case of improper design in a double ended side-mill or spot-facer. Each side of this tool has three teeth with the teeth placed opposite to each other. This is a badly balanced condition in the cross section of the piece and is made more serious by a sharp corner at the base of the teeth. Such a tool is almost certain to crack at the junction between the light and heavy sections. This condition may be corrected by staggering the teeth on opposite sides of the tool and introducing a generous fillet at the base of each tooth.

Fig. 8 illustrates two principles of design. This is a ring shaped section containing two keyways on opposite diameters. The keyway A is shown with absolutely sharp corners. This is never good design, and while millions of keyways are being made and used with sharp corners, this does not alter the fact that it is poor design, and every effort should be bent toward making standard a round cornered keyway such as is shown at B.

The second interesting point about this ring is that when it is quenched it will not stay round. The section of the ring is weakened through the two keyways, and almost invariably the ring will become oval. This condition may be corrected by cutting in two more keyways at 90° to the first two, as is illustrated in Fig. 9. These keyways may be of no use but they certainly do no harm, and their presence will balance the section and keep it round.

Another example of a shape which will almost certainly warp during heat treatment is shown in Fig. 10. Let us assume that this is a blanking die. Even though

Fig. 7—Improper design for a double-ended side-mill or spot-facer. This shows an unbalanced condition and sharp corners at the base of the teeth. (Only upper half of tool shown.)

Fig. 8

Fig. 9

Fig. 8—Correct and incorrect type of keyways. Sharp corners at "A" are incorrect design, while the rounded corners at "B" are correct. Fig. 9—Method of balancing keyways to avoid warping.

Fig. 10

Fig. 11

Fig. 10—A blanking die with center rib heavier than the surrounding areas, which often causes warping when quenched. Fig. 11—A similar die with holes drilled in the middle rib to equalize the amount of metal throughout the die, thus eliminating warpage difficulties.

this piece was made from an oil hardening, nonchanging, tool steel it would warp during quenching. The rib through the center would tend to prevent shrinkage in this direction, and the die would become oval. This figure is intended to illustrate a principle, and it is surprising how often it comes up in actual design. Certain portions of a die are held rigid by a web, while adjacent portions are unsupported, and warpage or distortion occurs during hardening which cannot be avoided without resorting to an air hardening steel. Frequently it is possible to avoid the difficulty due to such a rib by drilling holes, as illustrated in Fig. 11. Holes drilled for such purposes should always be of such size and so located as to help balance the section, rather than to unbalance it. Success in preventing warpage, and other forms of internal strain, will be directly proportional to success in balancing the weight of the sections and producing uniform cooling conditions.

Large dies of intricate design are sometimes made up in sections which often simplifies the problem of heat treatment.

To further illustrate the principles covered above and to assist in avoiding faulty design, Figs. 12-22 are given. Each illustration depicts one or more errors of design which is explained in the caption together with the danger encountered.

Fig. 12—A large reamer. When quenched the stresses will concentrate at the junction of the two holes at "A". Blind holes are poor design. Such holes should be continued throughout the entire length. A good fillet should be used at "B" in order to eliminate cracking from the sharp corners during hardening. The roots of the cutters should have good fillets as shown at "C" instead of the dangerous sharp angle at "D"

Fig. 13—A gear burnisher from which teeth were broken during hardening because practically no radius was provided at the roots of the teeth.

Fig. 14—Twist drills of this design gave considerable trouble in service from breaking at "A". When a more generous fillet was allowed, the trouble encountered was eliminated.

Fig. 15—A stem pinion with a keyway about one-half the diameter of the stem. The base of the keyway is extremely sharp, as shown at "A". The piece is further weakened by a hole drilled through the center of the stem near the keyway.

Fig. 16

Fig. 17

Fig. 16—A gage with the hole out of proportion to the outside diameter. This will cause the piece to go out of round or into barrel shape when quenched. Fig. 17—A cutter with the counter-bore too large for the design, which will cause the front end of the cutter to close in when treated.

Fig. 18—A dangerous design consists of thin collars adjoining thick sections. When hardening pieces of this design, the thin sections often crack from the hubs.

Fig. 19—A cutting tool with a very narrow cutting edge with a thick hub. When quenched the cutting edge will often warp or buckle.

Fig. 20—This shows the theoretical sharp points on cutting tools. These sharp points will burn off in hardening. They should have a small flat surface as shown at "A".

Fig. 21—When hardening, the concentration of strains at the junction of the two holes in the center will cause failure. Such holes should be plugged before hardening.

Fig. 22—A blanking die poorly designed. Crack will occur from point of fork prong to set screw hole. The position of the set screw hole should be changed to eliminate cracking.

Fig. 23—Longitudinal section of a cold drawing die. Stresses set up in heat treatment and in service concentrated at point "A" so a fillet should have been used to avoid chance of spalling at corners.

Fig. 24—Blanking die (oil hardening) from approximately a 3 x 1/2 in. section. Stresses set up in heat treatment and in service concentrated at points "A" and "B". A slightly larger section such as 3 1/2 x 3/4 in. probably would have eliminated failure.

Welding of Metals*

Scope—This article is intended to cover principally the metallurgical aspects of the art of fusion welding and also certain allied processes. With recent developments in fusion welding processes, this art has assumed a prominent place in industry and is being extensively used in the preparation and shaping of metal parts, and their fabrication into engineering structures. It is not the purpose of this article to go deeply into the detail of the technique or equipment involved in the application of the various processes, but attention will be focused on the essential elements for satisfactory welding, as well as also the inspection methods and testing procedure that are necessary for determining weld quality. Brief attention is paid also to the subject of safe practices as it concerns certain of the welding processes.

Fusion Welding—Definition—A weld may be defined as a localized union or consolidation of metals. While the several welding processes involve other factors in addition to the application of heat, the importance of the effect of heat in all practical welding operations should be recognized.

Welding as embraced in the scope of this article is usually employed to unite like metals for purposes where the union or joint will be called upon to develop strength and transmit stress. The above definition is broad enough to include certain subsidiary processes such as bronze welding and hard facing which involve unlike metals, although low temperature soldering will not be covered.

General Consideration—The metallurgical, chemical, physical, and thermal characteristics of the metals greatly influence their weldability. The weld has been defined as "a localized union or consolidation of metals." There are a number of processes whereby this "localized union" can be accomplished but all processes, now in general use, have three characteristics in common. First, the "union or consolidation" is localized; second, the metal in the joint must be heated above the critical point; and third, the weld is accomplished in a comparatively short period of time and frequently in a progressive manner. Thus a small volume in a large mass of cold metal is, in rapid succession, heated from room temperature to above the critical point and cooled to below a black heat again.

In fusion processes the temperature frequently goes well above the melting point and all temperatures within the indicated range are present at the same time in bordering zones. In addition to thermal changes, such as expansion and contraction, metallurgical effects such as crystallization and heat treatment, chemical reactions, and changes in physical characteristics, such as strength and ductility, throughout the temperature range required by the process, must be considered.

The simplest phenomenon which happens to metals on heating is, of course, expansion. This, in the initial stages, is purely a change of volume and in most metals is a completely reversible change regardless of the rate of heating or cooling. At the same time that they are expanding, most metals become increasingly soft, ductile, and weak, a fact that is an advantage and a disadvantage. Due to this fact stresses become dissipated and advantageously spread over the heated area because of the ease with which the metal can stretch and yield. On the other hand the low strength at these elevated temperatures makes it necessary to be certain that the piece being welded is free to move so that an undue load will not be placed on the hot metal. Some metals become so weak that it is necessary to support them to prevent buckling or change of shape.

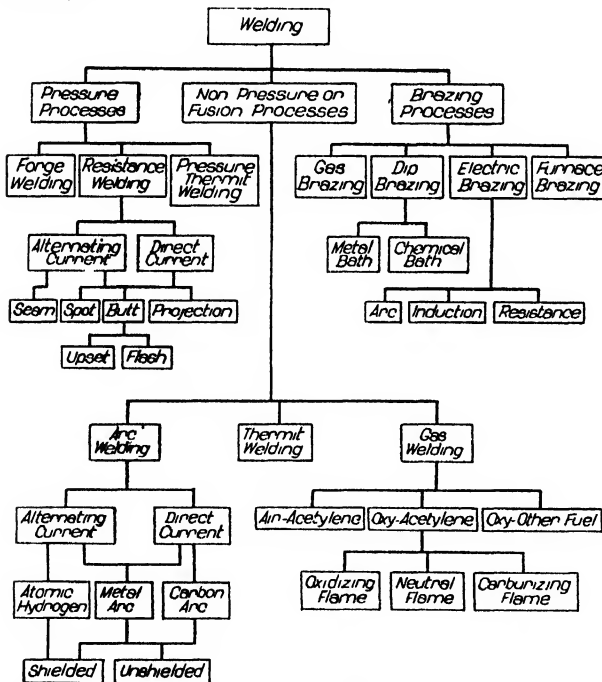

Particular attention must be paid to the final weld of a closed structure or in joining a light to a heavy section in order to reduce the internal stress in the structure to a minimum. Metals having a high rate of thermal conductivity present a particular problem in this respect since the heat is generally spread over a wider area and thus the expansion is greater, also such metals generally have a much greater reduction in strength on heating and frequently require support to prevent buckling.

*This article was prepared under the sponsorship of the International Acetylene Association, who appointed a special committee to handle the work. The International Acetylene Association felt that in order to do full justice to the subject, they should invite electric welding experts and users to join their committee. The full membership of the committee was as follows: C. W. Obert, Chairman, The Linde Air Products Co.; E. V. David, Air Reduction Sales Co.; L. D. Meeker, General Electric Co.; E. W. F. Smith, Lincoln Electric Co.; A. G. Wikoff, Union Carbide Company; C. H. Jennings, Westinghouse Electric & Mfg. Co.; H. L. Maxwell, E. I. du Pont de Nemours & Co., Inc.; and W. L. Warner, Watertown Arsenal.

Most common metals react with oxygen of the atmosphere. At higher temperatures the rate of oxidation increases rapidly. Nitrogen from the air also reacts with some metals forming nitrides which tend to increase the strength and reduce the ductility. This condition can be prevented by protecting the molten metal from contact with the atmosphere.

Because of the relative rapidity with which weld metal cools, consideration must be given to the effect of gases, either dissolved or entrapped, in the molten weld metal. In order to insure sound weld metal, free from porosity, the molten metal must be freed of these gases before it solidifies.

The fusion welding processes involve metals under the effect of heat and therefore are subject to the same thermal, chemical, physical, and metallurgical manipulations commonly known in the manufacture of metals. In steel welding, for example, the weld is in some respects a steel casting made in a steel mold and the metal of this casting comes either from the steel mold itself or from a combination of it and the welding rod or electrode. In gas welding the heat is applied to both the mold and the rod from external sources. In arc welding the heat results from electrical energy which passes through both the electrode and the mold. The welding processes are shown in the following chart prepared by the *American Welding Society*:

Pressure Welding Processes

Forge Welding—This is the oldest process of welding and is the only one whose general practice antedates the twentieth century. It is essentially a process of joining metal pieces that have been heated at the place of joining, to a condition that approaches plasticity on the surface. As soon as the plastic condition is reached the parts are quickly superimposed and worked into complete union either by hammering or pressure. The hammering is performed either manually or by machine and the force of the hammering or pressure is dependent largely upon the size and mass of the pieces or parts being joined.

Resistance Welding—

General—In this process of welding, the surfaces to be joined are heated to

the plastic condition by the passage of a heavy localized electric current accompanied by mechanical pressure to bring the parts into complete union. To produce the required heavy current at low voltage, the employment of alternating current has been found most convenient as it is possible by the use of suitable transformers to obtain almost any desired combination of current and voltage. Only in special cases is direct current used for this purpose.

An important feature in all resistance processes is the composition of the electrode, which must possess good thermal and electric conductivity combined with maximum hardness and sufficient strength. A combination of these requirements has been achieved to a high degree by the use of a hard copper electrode faced with one of several alloys whose hardness under welding conditions is much greater than that of copper.

Resistance—Butt Welding—In the butt welding form of the resistance process, pieces are mechanically gripped and pressed together while heat is generated by

passing a large electric current through the area of contact. The original upset method is a form of butt welding in which high mechanical pressure is applied and maintained throughout the operation, the temperature being kept below melting. The extruded metal is upset into a roughly convex form which, if desired, may be molded to a predetermined shape in a die, thus securing a kind of drop forging, or it may be ground off. Today the upset method is generally combined with flashing. The flash method as first developed is a form of butt welding in which, after initial contact and heating, there is a brief period during which the parts are slightly separated, thereby causing intense arcing. The weld is then completed under pressure and at a temperature sufficient to bring to a plastic state a portion of the metal, part of which is extruded in the form of a thin burr which may be ground off. This method is still followed on large work, but on smaller work the flashing effect, which in the original process was secured by separation of the parts, is obtained by an automatic successive adjustment of pressures. There is no hesitation in the cycle and as a result this form of flash welding is quite rapid.

Resistance—Spot Welding—In the spot welding form of the resistance process, two or more sheets of base metal are held between metal electrodes which pass a large current of fairly low voltage through the sheets. Immediately following this, and with current maintained, the electrodes are forced together with sufficient mechanical pressure to unite the surface of the sheets in a spot whose size is approximately that of the end of the electrodes; this pressure is maintained until after the current has been cut off.

Resistance—Projection Welding—Projection welding is a form of resistance welding wherein small projections are formed on one or both pieces of base metal. The projections serve to localize the current.

Resistance—Seam Welding—The seam welding form of the resistance process is a series of overlapping welds. Two or more sheets of base metal are usually passed between electrode rollers, which transmit the current and also the mechanical pressure required to produce a welded seam. A current interrupter is generally used for this type of weld.

Resistance—Percussion Welding—The percussive methods of resistance welding differ from the usual forms of resistance welding in that (1) a direct current supply is essential; (2) there is a sudden discharge of electrical energy at the junction, with an arc, which is extinguished by a percussive blow; and (3) the surfaces united are partially fluid. The energy may be supplied by either the discharge of a condenser (electrostatic) or transformed by the collapse of a magnetic field (electromagnetic).

Thermit Pressure Welding—This is another plastic welding process and it differs from the forge and resistance welding processes principally in that the heating to plasticity is obtained from the thermit chemical reaction rather than from fire or electric current.

The chemical reaction which generates the required heat for welding is described later in this article under the heading "Thermit Welding." The molten steel and alumina slag are conducted around the abutting ends to be welded in such a manner as to localize the heating, as near as possible, at the joint. This requires the use of a suitable mold, which is usually made of light cast iron segments, which can be clamped in position and then easily removed after the thermit reaction. This thermit reaction is so handled that the alumina slag enters the mold first and leaves a coating on it and the ends being joined, thus protecting these parts from the superheated iron. The passage of the iron through the mold brings the work up to welding temperature in a short time which varies from a few seconds to several minutes, depending on the size.

Fusion Welding Processes (Nonpressure)—These processes differ from the three previously enumerated in that they depart from the union of plastic metals and utilize fusion of metal to effect the desired union. The joining is accomplished by the fusion of metal upon or between the surfaces of the parts being united, the fused metal being generally obtained by deposit from an external source, although in some instances the abutting edges are merely fused together to form the joint.

Gas Welding—In this process the heat is supplied by the combustion of a suitable fuel gas with atmospheric or pure oxygen. The fuel gas and oxygen are mixed in a suitable torch and so regulated as to produce an impinging flame having the desired characteristics. The gases most commonly used are oxygen and acetylene although hydrogen and other combustible gases are used to some extent.

Oxy-Acetylene Welding—Oxy-acetylene welding is a form of fusion welding wherein the heat required is supplied by the oxy-acetylene flame. Usually in fusion welding a filler metal is added in the form of welding rod to form the welded joint, although joints in some instances are formed in oxy-acetylene welding merely by fusing together the parts to be joined without the addition of welding rod. As a means of floating out impurities or aiding in obtaining a satisfactory bond, flux is employed in the welding of some metals, such as cast iron, certain alloy steels, and the nonferrous metals.

In the combustion of acetylene and oxygen the resulting flame has characteristics which indicate whether it is reducing or oxidizing in character. If the acetylene and oxygen are in proportion, a neutral flame results. In most gas welding the neutral flame is recommended, but in certain welding applications, however, a

slightly carburizing or slightly oxidizing flame is considered desirable. Certain of the alloy materials are welded to advantage with a slightly reducing or carburizing flame and under certain conditions a reducing flame is considered desirable in the welding of steel materials.

An important characteristic of the oxy-acetylene flame lies in the protection of the molten metal from atmospheric attack by the outer envelope of the flame. The surrounding oxygen at this point is consumed in the final combustion stage of the flame.

Arc Welding—In arc welding, the surfaces to be joined are fused by the heat of an electric arc. There are three forms of arc welding, each of which derives its name from an identifying element of the process of applying it, such as the electrode material used or the means of heat transfer. They are carbon arc welding, metallic arc welding, and atomic hydrogen arc welding.

Welding current for carbon arc welding is always from a direct current source. Metallic arc welding utilizes either direct or alternating current. Atomic hydrogen arc welding generally is done with alternating current. Direct current for arc welding is usually obtained from a motor generator set. The generator may be of either the variable-voltage single-operator type or specially designed constant-voltage multiple operator type with suitable controls. Rectifier units are also used for this purpose. For alternating current two methods are used: (1) The static transformer, which is a single phase unit specially designed for arc welding. Various methods of control are used, but all are of variable-voltage single-operator type; and (2) The

*For complete combustion of acetylene, 1 molecular volume (380 cu. ft. at 60°F.) of acetylene plus $2\frac{1}{2}$ molecular volumes of oxygen burns to form 2 molecular volumes of carbon dioxide plus 1 molecular volume of water vapor, liberating 542,700 B.t.u. of heat.

alternating current method of rotating frequency changer sets, which convert the usual frequency to several times that of the supply line.

Carbon Arc Welding—In this process the arc is usually drawn between a carbon, or graphite pencil or electrode, and the work. The heat of the arc causes fusion of the base metal and, in case additional metal is required, it also fuses a filler rod which is fed into the joint at the desired rate. This process of welding may be accomplished either by hand or mechanical methods, the latter being commonly called "automatic carbon" arc welding. The hand process is used only on special applications, largely on account of the erratic nature of such an arc. In the automatic process the arc is controlled by superimposed magnetic fields.

Unshielded Carbon Arc Welding is a term applied when either form of carbon arc welding is performed without the aid of appreciable amounts of flux. This process when applied to ferrous materials is used on relatively unimportant joints only, but by proper procedure it is used in the welding of deoxidized copper to considerable extent.

Shielded Carbon Arc Welding comprises the use of fluxes which may be in the form of treated paper, powder, paste or gas, or a combination of these. These fluxes have various functions, among which are: To envelop the molten metal in a noncontaminating atmosphere to the exclusion of the oxygen and nitrogen of the air; to scavenge impurities from the molten metal, to retard the cooling rate of the weld metal, and to produce weld metal of the desired physical properties. This process is applied to most of the important joints to which the carbon arc is suited, generally in automatic form.

Arc welding with bare electrode.

Arc welding with shielded electrode.

Metallic Arc Welding—In this process the arc is struck between a metal electrode and the work. The heat of the arc not only fuses the work but also the electrode, which is in the form of a wire of suitable material. This fused electrode material passes through the arc and unites with the fused base metal to form the welded joint. The process is adaptable to either hand or automatic methods. There are two major classifications of metallic arc welding, *unshielded* and *shielded*. The former term is applied when the electrode is either a bare wire or is lightly coated with small amounts of flux and sometimes called a wash or dust coated electrode.

In shielded metallic arc welding the metallic electrode is covered with a thick layer of fluxing ingredients with or without a fibrous binder. These flux coverings function in several ways to produce weld metal of high physical properties and comparable to the base metal:

1. They usually are consumed more slowly than the metal of the electrode and therefore form a cupped end which constitutes a partial mechanical shield for the arc from the air.
2. Combustion of the fluxes produces an envelope of gases around the arc, which excludes oxygen and nitrogen of the air from contact with the molten metal of the weld.
3. The fluxing ingredients scavenge impurities from the molten metal of the weld.
4. A protective slag covering is formed which covers the top of the weld and protects the molten metal from contamination by oxygen and nitrogen from the air; it also retards the cooling rate and thus partially heat treats the weld.
5. Alloying elements desired in the weld are sometimes supplied in the heavy flux coverings.
6. Materials are sometimes placed in the coatings to increase the arc stability by virtue of their ease of ionization or greater electron emission. Materials may also be added to make the

flow of metal across the arc more uniform by reducing the adhesive force between the molten metal and the end of the electrode or by changing the surface tension of the molten metal so that globular formation is smaller and more uniform.

Shielded arc welding controls the metallurgical processes involved in forming a weld to such an extent that greater amounts of heat are generally used than without shielding. This results in greater welding speeds and at the same time physical properties equal and often superior to those of the base metal.

The average bare electrode deposit has from 0.11-0.15% nitrogen and about 0.3% oxygen (as oxides), while a shielded arc electrode deposit contains from 0.010-0.023% nitrogen and about 0.068% oxygen. A comparison of the physical properties is as follows:

	Bare Electrode	Shielded Arc Electrode
Ultimate tensile strength, psi.....	40,000-60,000	65,000-85,000
Elongation in 2 in., %.....	5-10	20-30
Izod impact, ft.-lb.	5-15	50-80
Fatigue, psi.....	12,000-15,000	28,000-32,000
Specific gravity.....	7.5-7.7	7.82-7.86
Corrosion resistance.....	poor	better than mild steel
X-ray.....	considerable porosity	practically no defects

Atomic Hydrogen Arc Welding—In the atomic hydrogen arc welding process an alternating current arc between two tungsten electrodes in a stream of hydrogen gas furnishes the source of heat. The arc column is defined by a thin brilliant line which forms a loop under the influence of its own magnetic field and the streaming gas. In this arc column, which has a temperature between 6000 and 6500°F. absolute, the hydrogen molecules are completely broken down into atoms, and during this process a great deal of energy is absorbed. When this atomic hydrogen flame, which is coincidental with the arc column, is placed in contact with the metal parts being welded, the dissociated hydrogen atoms recombine into molecules, giving to the surface the heat which was absorbed during dissociation. The weld metal may be supplied as surplus metal from the parts being welded, or be added from a filler rod. The atomic hydrogen arc is surrounded by an envelope of hydrogen gas which protects the work and electrodes from oxidation and reduces existing oxides in the metal. The size of the atomic hydrogen arc may be adjusted by the operator by changing electrode separation during operation; in this way an arc varying in size between $\frac{1}{8}$ in. and over 1 in. is obtainable. The freedom from oxidation, the intense concentration of heat, the flexibility and ease of operation, combined with freedom from magnetic blowing effects, are features which characterize atomic hydrogen arc welding.

Thermit Welding—The thermit fusion process, commonly known as thermit welding, originated with a discovery made in Germany, about 1900, by Dr. Hans Goldschmidt. He found that if a mixture of a metallic oxide and finely divided aluminum were ignited at one spot, the two materials would react exothermically and the reaction would progress throughout the mixture, thereby converting it into two new materials, a superheated mass of the metal itself and a slag composed of molten aluminum oxide (alumina). He further found the reaction would progress so rapidly that in the case of most metals as much as a ton of material could be converted from a cold mixture in half a minute. Later the most suitable kind of iron oxide (Fe_2O_3), the best size of its flakes, and the proper percentage of its fineness for use in welding steel were determined, as well as the possibilities resulting from the addition of such elements as chromium, nickel, vanadium, and manganese to a thermit steel mixture.

In the thermit process the parts to be united are separated by a space, the extent of which depends on their size. The surfaces are thoroughly cleaned by sand blast or otherwise. Usually the space is given the form of a parallel-sided gap cut by means of a gas torch, the slight layer of oxide resulting from the cutting process being apparently beneficial. Around the parts a wax pattern is formed whose shape is that of the reinforcement desired. A sheet iron box is placed around this pattern with a space between it and the pattern, and when the wax has hardened, sand is rammed into the space, provision being made for the proper number of risers and pouring and heating gates. The wax is then melted by directing a flame into each heating gate, and as the wax flows away it leaves clear the space to be occupied later by the thermit steel. Heat is continued so as to dry out the sand mold

and to bring the parts to be united to a red temperature. If multiple sections are to be welded, a two-part mold and a special wooden pattern may be substituted for the box and the wax.

A proper thermit mixture is then placed in a crucible supported over a pouring gate or gates, and when the work is ready it is ignited. In about half a minute the reaction is complete and the thermit steel is then tapped from the bottom of the crucible into the pouring gate. The superheated metal flows around and between the parts to be united, thoroughly combining with their surfaces and welding them into one homogeneous mass, while the molten alumina slag overflows into a basin on top of the mold.

Process Chart for Welding—Table I gives the welding methods that are commonly used and those occasionally used for a number of ferrous and nonferrous metals and alloys.

A. Iron—1. Wrought Iron—The low carbon and high slag content have a marked effect upon the weldability of wrought iron.

Forge Welding—Wrought iron is an ideal material for forge welding.

Resistance Welding—Spot, seam, projection, flash and resistance butt welding may be applied satisfactorily to wrought iron. To produce solid, clean welds and to prolong electrode life all scale, oxide and other foreign matter must be removed from the work.

Thermit Pressure and Fusion Welding—Wrought iron can be successfully welded by either of these processes. If the iron contains heavy layers of slag included, it is sometimes necessary to make two thermit welds to accomplish a satisfactory joint. In the fusion thermit welding process the superheated thermit steel melts the adjacent parent metal to the extent that heavy slag layers may introduce porosity into the thermit weld itself. This occurrence can then be avoided. The collars may be trimmed and the original vee cut through the thermit steel weld, and the gap immediately rewelded. By this method, the new weld fuses only as far as the original weld and almost invariably is sound because the slag of the wrought iron has already been eliminated from this section.

Gas Welding—In oxy-acetylene welding of wrought iron, the slag content sweats to the surface at a comparatively low temperature. This may deceive the inexperienced operator who may regard it as an indication of fusion. Heating must be continued until the base metal itself actually breaks down into a puddle.

This puddle of molten metal must be maintained and the welding rod kept immersed in it to assure fusion and penetration without oxidation. Excessive stirring of the puddle should be avoided as this causes undue exposure and resulting oxidation.

Oxy-acetylene welding rod for wrought iron should either be a low carbon rod or should contain sufficient manganese and silicon so that a weld metal relatively high in these elements will be obtained. The welding flame adjustment should be strictly neutral.

Arc Welding—Arc welding of wrought iron both in flat and vertical positions with coated electrodes is handicapped by accumulations of slag which become trapped in the weld and care must be taken to melt it out. It is customary to melt as little as possible of the wrought iron, and reverse polarity reduces this handicap substantially but not entirely.

The welding of wrought iron with bare electrodes is comparable to welding of low carbon steel. The arcing characteristics of the electrode and the ability to obtain proper fusion between the parent metal and the deposited weld metal are typical of those obtained in welding mild steel.

The strength of welds made with mild steel bare electrodes shows that the weld strength is approximately equal to that of the parent metal, while the weld made with mild steel heavily coated electrodes is greater than that of the parent metal.

Bronze Welding—The bronze welding process is readily applicable to wrought iron.

2. Low Carbon Iron—Iron with a carbon content of 0.06% maximum is one of the most readily welded of the ferrous metals.

When welding low carbon steels preheating is not necessary and subsequent annealing is not required unless it is desired to eliminate the residual stresses set up during the welding operation.

Forge Welding—Low carbon iron is readily welded by the forge welding process.

Resistance Welding—Low carbon irons are readily resistance welded by any of the processes adopted for the welding of wrought iron.

Code: A—Commonly used. B—Occasionally used under favorable conditions. No—Not used.
(..)—No information available.

Gas Welding—This process is applied similarly to that in the case of low carbon steels except that the filler rod utilized is of low carbon iron which is necessary in order to retain the corrosion resisting properties of the parent metal and to obtain a weld of similar characteristics.

Arc Welding—Arc welding of low carbon iron is accomplished with the use of mild steel, heavy coated electrodes. The welding current and procedures are the same as for welding mild steel. Bare electrodes can be used with a resulting decrease in the corrosion resisting properties of the weld and adjacent parent metal. Iron with carbon content below 0.15% absorbs gas readily from the atmosphere during the welding. For the highest quality weld, complete shielding is necessary.

Bronze Welding—Low carbon iron may be bronze welded quite readily by either the arc or gas process. This does not require the heating of the steel to as high a temperature as is necessary for fusion welding, which is a decided advantage.

Thermit Welding—Iron with a carbon content of 0.06% and less can be successfully welded both by the thermit fusion and pressure processes.

B. Carbon Steels—1. Low Carbon Steel (Up to 0.30% Carbon)—These steels are easily welded by all the welding processes and the resultant welds and joints are of extremely high quality.

Gas Welding—The joint edges should be clean and properly prepared to facilitate good fusion and a sound weld. When welding long seams, allowance must be made for the effect of heat along the line of weld which causes contraction during cooling and tends to pull the unwelded ends of the plates together. The normal spacing that is allowed in welding is $\frac{1}{4}$ in. opening per ft. of seam. Faster welding speeds will materially reduce the amount of contraction obtained. When making fillet welds the overlapping plates should be held close together.

A neutral flame is frequently used when welding steel of this class. Increased welding speeds are possible, however, by using a slightly reducing flame. This type of flame carburizes the kerf surfaces, thereby lowering their melting temperature and making possible fusion of the deposited metal to the plates at a temperature lower than would normally be required. Welded joints made in this way are of high quality and the fusion zone is not hard or brittle.

The preference for filler metal at the present time is for the so-called high test welding rods with about 0.15-0.20% carbon and certain metallic elements that will insure freedom from included oxides and give the proper fluidity in the molten metal.

Arc Welding—Low carbon steels are readily welded by all forms of this process. Many types of electrodes may be used such as bare, dust coated, washed or dipped, shielded arc, or flux coated. Carbon arc welding is also practical on these steels and the results obtained are a function of the technique employed.

When welding long seams the progressive shrinkage of the deposited metal tends to pull the plates together. This is less severe than with gas welding and an allowance of $\frac{1}{4}$ in. per ft. is sufficient to take care of this condition. Proper clamping and tacking and the adoption of special welding procedures such as the step back and skip procedures are commonly used to prevent distortion and residual stresses. The design of the structure, preparation of joint, size of electrode used, the welding current and voltage are of extreme importance.

Carbon arc welding varies from metallic arc welding in that the arc is drawn between the base metal and a carbon or graphite electrode. The arc heat in this case is used only to melt or fuse the base metal and the addition of filler metal when required must be obtained by a specially prepared flange or upset edge at the joint or from some extraneous source. The latter method of adding filler metal can be accomplished by placing additional metal on the seam to be welded or by feeding it into the weld in a manner similar to that employed by the oxy-acetylene process.

Carbon arc welding done without the presence of a flux or shielding atmosphere may result in brittle welds. Shielding the arc by painting the weld with a special flux or by introducing a suitable fluxing material into the arc produces welds of high quality.

Bronze Welding—Low carbon steels may be bronze welded quite readily. The joint surfaces are "tinned" through the use of a suitable flux and bronze welding rod. The bronze is then melted into the space between the tinned surfaces to be joined. This work is ordinarily done as a continuously progressive operation, the tinning being carried out for a distance and then additional bronze being deposited before the section becomes cold. With recently developed bronze rods, strengths of welds of the order of 55,000 psi. can be obtained. This process does not require the

heating of the steel to as high a temperature as is called for by fusion welding which is often a decided advantage.

Thermit Welding—Fusion thermit welding is successfully carried out on low carbon steels by using forging thermit. The welds give tensile strengths of 70,000-75,000 psi., elongations of 15-20% in 2 in., and good impact values. Before welding the joint surfaces are preheated to 1600-1700°F. The purity of the weld deposit eliminates the need of subsequent forging or heat treatment in order to develop satisfactory physical properties.

2. Medium Carbon Steel (0.30-0.50% Carbon)—Steels in this class can be welded with the various fusion processes. The technique and materials used are dictated by the metallurgical characteristics of the base metal. In some cases preheating and subsequent heat treatment may be required to produce the desired weld quality. This condition is especially true for steels containing over 0.40% carbon.

Gas Welding—In welding this material better welds can be obtained if an excess of acetylene is used in the welding flame. The recommended welding procedure is similar to that for low carbon steels. As a rule little trouble is experienced from the formation of hard and brittle constituents as a result of rapid cooling. The quality of the finished joint will be improved if it is heat treated after welding.

Arc Welding—The weldability of steels of this grade depends upon the carbon content of the base metal because the rapid cooling may produce a martensitic or troostitic structure. The formation of martensitic or troostitic structures in the fusion zones tends to make these areas hard and brittle and of an undesirable condition.

Preheating temperatures of 300-500°F. have been found effective in eliminating and reducing the formation of hard and brittle areas. By heating to 1100-1200°F. it is possible to restore the desired properties in the areas affected by the welding heat.

Shielded arc electrodes of the type used on low carbon steels are satisfactory for the welding of steels in this class.

Thermit Welding is carried out as successfully on these steels as on the lower carbon grades. Forging thermit is generally used but the increase in carbon from the parent metal produces a somewhat higher tensile strength and lower ductility than is the case when welding the lower carbon steels.

3. High Carbon Steels (0.50-0.90% Carbon)—Because of the higher carbon content, steels of this type are more difficult to weld.

Gas Welding—As these steels are often heat treated the welding heat will affect such treatment and produce a joint of different properties than those possessed by the original metal. Care should be taken to prevent overheating of the parts and the weld should be completed as quickly as possible. These materials melt at a lower temperature than the lower carbon steels and tend to spark when overheated, a condition which aids from overheating the parts.

A carburizing or excess acetylene flame is advantageous in securing strong sound welds. High carbon filler rods are often used although satisfactory results can be obtained with medium carbon filler metal, which produces a weld of moderate strength but the increase in ductility is often beneficial. By heat treating after welding it is possible to eliminate the effect of the welding heat and to improve the strength of the weld.

Arc Welding—Steels in this group do not give good properties after arc welding. Hardness and brittleness may be obtained in the fusion zone. For the best results, it is recommended that the parts be preheated to at least 500°F. before welding and subsequently heated to 1200-1450°F.

Welding on these steels is often done to rebuild a worn surface or to develop a hard wear resistant surface. In such cases unless the carbon content of the parent metal approaches the upper limit, preheating or subsequent heat treatment are not necessary.

Mild steel electrodes of the shielded arc type can be used to make joints on these steels. The deposited metal tends to absorb carbon from the base metal so loses considerable ductility. Austenitic electrodes are often recommended and the resultant welds have good physical properties but the fusion zone may still be hard and brittle.

Thermit Welding—These steels are readily welded by the fusion thermit process. Slightly lower preheating temperatures are used than is the case with the lower carbon steels because of the lower melting temperatures of the parent metal.

If forging thermit is used the pick up of carbon will be sufficient to produce a

weld strength of 90,000-100,000 psi. In many cases, however, hardness or wearing qualities are of prime importance and special thermit is required.

The preheating and inherent characteristics of the thermit process eliminate the rapid cooling obtained in arc and gas welding, consequently subsequent heat treatment of joints even on these high carbon steels is not required for satisfactory physical properties.

4. Tool Steels (0.80-1.50% Carbon)—These steels are relatively difficult to weld.

Gas Welding—Drill rods, available in the various diameters required for welding and of carbon content sufficiently high to cover the carbon range are generally used in welding these steels. The use of a carburizing or excess acetylene flame adjustment is advantageous in securing sound strong welds. Flux suitable for cast iron welding should be used sparingly. Preheating and annealing are usually necessary.

Arc Welding—Because of the heat effects of arc welding it is seldom used for steels of this type. If welding is required, one of the following procedures is recommended:

(1) After annealing, preheat the parts and weld with a suitable shielded arc electrode followed by heat treatment to restore the desired properties. (2) Preheat the parts and use an austenitic electrode. Preheating will aid in preventing the formation of a hard fusion zone and the weld will not be hard because of its austenitic condition. (3) Preheat the parts and deposit one or more layers on the kerf surfaces of the parts with a shielded arc electrode. These layers dilute the carbon so that the parts can then be more readily welded together. It should be noted that this process does not produce a high carbon weld.

Thermit Welding—Fusion thermit welding is not commonly used on these steels, but successful joints have been made on materials with carbon contents of 1.10%. Forging thermit can be used but the tensile strength will not be equivalent to that of the parent metal. Higher carbon thermit can be used if the strength is of prime importance. Heat treating the weld and fusion zone after welding is recommended in order to produce the best properties.

5. Copper Bearing Steels—These steels are generally of the low carbon variety and contain from 0.20-0.30% copper. The same welding processes are applicable as for ordinary steels of the same carbon range. Welded joints made by the gas or shielded arc processes are in general as resistant to corrosion as the copper bearing steels.

C. Cast Steel—Welding of low carbon steel castings presents no particular difficulties if the casting is properly prepared, is reasonably clean and the ordinary precautions are taken to avoid setting up excessive expansion and contraction stresses in the metal. With carbon content of the casting above 0.25% and with special alloy compositions, certain precautions are necessary in applying welding.

1. Plain Carbon Steel Castings—Before welding steel castings an effort should be made to learn the analysis in order to weld successfully the high carbon and the alloy castings. Castings under this heading should not exceed 0.25% carbon and a negligible amount of alloying materials. Castings of such analyses present no difficulties in welding and can be handled approximately the same as for low carbon rolled steel.

Gas Welding—It is customary to use a general purpose filler rod for welding these castings although for the best results the analysis of the filler metal should be similar to that of the base metal.

Arc Welding—The procedure for electric arc welding steel castings (low and medium carbon) is essentially the same as for rolled steel of similar analysis. For the best results a high grade heavily coated electrode is considered desirable. The surfaces to be welded should be carefully cleaned of sand inclusions, cracks, porosity and dirt. Multilayer welding and high currents should be employed if the carbon content is low, but small diameter electrodes and low currents are necessary when the carbon content is high, while in some cases preheating and slower cooling are desirable.

Bronze Welding—Bronze welding is satisfactorily applied to steel castings, especially where the difference in surface appearance of the casting is not objectionable. Both gas and electric arc processes are used, the only preparation necessary being that involved in preparing and cleaning the surfaces to be welded as described above under Low Carbon Steels.

Thermit Welding—Repairs are readily made and heavy cast steel parts are commonly reclaimed by the thermit process. Where the work consists of applications such as replacing teeth in large gears or pinions, the fact that the tooth is a com-

paratively small projection on an extremely heavy casting must be taken into account. If the casting were preheated at the weld only, the heat would be carried away into the casting so rapidly that fusion between the weld metal and the parent metal could not be obtained. It is therefore necessary to preheat the entire casting. Forging thermit may be used for this work, although where parts are subject to abrasion and wear, "wabblers" thermit, providing a hard wear resistant machinable steel, may be employed.

2. High Manganese Steel Castings—Welding these castings is mostly for the purpose of restoring portions worn away or for the repair of cracked and broken pieces. The manganese content is frequently as high as 12% or more, and the carbon content ranges from 1-1.40%.

Resistance Welding—Electric resistance welding of manganese steel parts has not been used to any great extent because of the difficulties that have been encountered in obtaining strong welds by this method. It is possible, however, that resistance welding can be successfully used by proper adjustment of current and time of application.

Gas Welding—In welding these castings a shallow zone must be heated to a temperature close to 2200°F. and the filler metal then applied. The use of a rod of the same manganese content as the casting should be used, and if in addition the rod contains from 3-5% nickel its use will produce reliable welds. The high nickel content tends to inhibit embrittlement under slow cooling so that no quench is necessary.

Arc Welding—In arc welding high manganese steel (12-14% Mn and not over 1.25% C), a shielded electrode of a type to give properties in the deposited metal approximately the same as the base metal should be used. The weld should be in an austenitic condition even after slow cooling, and the welded part should not be quenched because of the danger of cracking. The weld deposit is in such cases rather soft but upon cold working will produce a hardness of 45-50 Rockwell C.

Thermit Welding—Thermit welding of manganese steel is not generally practiced because of the effect upon the adjacent steel of the heat of the weld. A fairly successful weld can be made if the whole mass can be preheated and then heat treated after welding, but this is not always possible.

3. Alloy Steel Castings—Alloy steel castings are in general welded by the same process as is used for rolled alloy steel of the same composition. The number and character of the alloying elements have a decided effect on the welding properties of the castings.

Resistance Welding—Electric resistance welding has not been applied to any extent to alloy steel castings because of the varying forms and contours of the castings commonly encountered. It is possible, however, that resistance welding can be applied if the work is held in suitable jigs and there is proper adjustment of current and time of application.

Gas Welding—It is customary to modify the filler rod from the type used in welding carbon steel castings so that the weld deposit will be similar to that of the alloy casting. The same requirements for fluidity of deposit are necessary as in the case of carbon steel castings, in order that impurities may be brought to the surface in the melting operation.

Arc Welding—The procedure for electric arc welding of alloy steel castings is quite similar to that used on carbon steel castings, the only modification being in the coating of the electrode which should be so proportioned as to influence the weld metal deposit. It is customary to use heavily coated electrodes for this purpose and the surfaces to be welded should be thoroughly cleaned before welding. In some cases preheating is considered desirable, and in practically all cases a heat treatment after the welding is completed is desirable.

Thermit Welding—With the thermit weld metal, it is possible to match the composition of the casting by the addition of metallic elements to the thermit mixture.

D. Cast Iron—**1. Gray Iron**—In welding gray cast iron, preheating is usually necessary to avoid stresses. Gray iron castings may be welded hot and then allowed to cool slowly so as to maintain their characteristic gray iron structure. Only in certain cases where the structure of the weld metal is of little importance can preheating be avoided.

Forge Welding—Gray cast iron cannot be forge welded.

Gas Welding—Gray iron castings should be preheated to a low red heat and welded while hot with a cast iron welding rod containing a high percentage of

silicon. A suitable flux should be used to remove oxides. When the weld is completed, the whole casting should be allowed to cool slowly to room temperature. With this procedure the weld will be strong, yet soft and machinable.

Arc Welding—Preheating the casting to a dull red heat accelerates the welding, relieves strain and reduces the tendency toward unmachinable spots and cracks, and helps to retain the characteristic gray iron structure. Excessive strain or breakage may be encountered in welding gray cast iron which may be intensified by a hard area, containing carbides of iron, outside the weld. For this reason castings lighter than $\frac{1}{4}$ in. are seldom welded. It is desirable that the casting be annealed after welding.

Special electrodes, either coated or uncoated, which give a good bond with the casting are used. A rather low current should be used, and the welding done intermittently. Each bead should be slightly peened and allowed to cool slightly before depositing the next bead. All of these considerations tend to reduce the hardening effect along the line of fusion. Where machinability is of primary importance and strength is of secondary importance, nonferrous electrodes such as high nickel (67%) are available. These electrodes produce a soft, machinable deposit without any tendency to harden at the fusion line. This deposit is also advantageous where appearance is important, since the color matches that of the cast iron.

Bronze Welding—When gray iron castings are bronze welded, comparatively little preheating is necessary. When the base metal is raised to a temperature of 1500-1600°F. the bronze will "tin" the cast iron surface, and make a bond as strong as, or stronger, than the cast iron.

When bronze welding with the arc, preheating is generally unnecessary, but it should be kept in mind that too much current is detrimental to satisfactory welding and the currents used should be as low as possible consistent with the size electrode and part being welded.

Thermit Welding—The thermit process, while entirely suitable for welding gray iron, cannot be used on all castings because of the difficulty of allowing properly for shrinkage of the weld metal when it cools. Contraction of thermit steel is approximately double that of cast iron so that, generally, if the length of the crack to be welded is more than eight times the thickness of the section, the difference in shrinkage along the line of fracture will result in small hairline cracks in the weld.

2. **Malleable Iron**—Fusion welding of malleable castings is generally regarded as unsatisfactory (even when the castings are remalleableized afterward). For this reason repairs to malleable castings are generally made by bronze welding. Malleable iron foundries frequently reclaim defective castings by fusion welding the white iron castings before malleableizing.

Gas Welding—For the oxy-acetylene welding of defective white iron castings before malleableizing, white iron welding rods of the same approximate analysis are used. The salvaged castings are then put through the malleableizing process.

Arc Welding—Malleable iron castings can be welded with the arc process using low heat. In general, these castings should be treated the same as gray cast iron, using the same precautions and procedure. After welding, the casting should be put through the same annealing process by which it was originally made. Annealing is helpful if full heat treatment cannot be given.

Bronze Welding—The temperature of 1500°F. required in the base metal for bronze welding is not so high as to affect seriously the properties of malleable iron, so effective repairs can be made by this process. Either the gas or arc may be used.

3. **Alloy Cast Irons**—The welding procedures for most alloy cast irons are essentially the same as for gray iron. Filler material should be of the same alloy content as the base metal, or if such material is not available the welds should be made with high quality gray iron rod. For arc welding, see under "Cast Iron."

E. Low Alloy, High Tensile Steels—The low alloy, high tensile steels are readily welded by the various welding processes. The amount of alloying element in these steels is only slightly greater than in ordinary mild steels and is considerably less than in many alloy steels. These steels have higher physical properties than carbon steels and usually possess higher resistance to atmospheric corrosion. When welding these steels by a process wherein metal is added, the metal need not necessarily have the same composition (provided it has the same physical properties), unless resistance to corrosion is a factor, in which case the weld metal should be of a composition similar to the base metal. Heat treatment is desirable for the various alloys, to develop the required physical properties.

Gas Welding—Where the strength is of importance, a welding rod of the high

test steel type will give satisfactory results in oxy-acetylene welding. Where corrosion resistance is a factor, the welding rod should be of the same composition as the base metal.

Arc Welding—When arc welding these materials, a shielded arc type of special electrode is generally used.

Thermit Welding—Through the addition of metallic elements to the thermit mixture, either by means of metallic pieces, which are melted during the reaction, or in the form of combinations of oxides of the required elements with aluminum, a wide variation in the analysis of thermit steel is made available so that it is entirely possible to match the analyses of a number of low alloy steels. The following are chemical formulae of the aluminum reduction of several oxides used for this purpose:

Since these steels are used mainly for developing strength, ductility, resistance to shock and resiliency, it is usually desirable to heat treat the welds made in these steels. The heat treatments recommended for these alloys are given below.

1. **Plain Nickel Alloy Steel**—While the 3-3½% nickel alloy steels do not necessarily need heat treatment if the carbon content does not exceed 0.25%, such alloy steels with carbon contents over 0.25% require a preheat of from 300-600°F. Steels in this class have a tendency toward air hardening and they require slow cooling in order to retain the desired physical properties.

2. **Nickel-Copper Alloy Steels**—The alloy steels in this class contain from 1-2% nickel and 1-1.6% copper, while the carbon content is usually limited to 0.25% as a maximum. No preheat is required for the ordinary welding of these alloys except when the carbon content exceeds 0.20% when in some cases it is considered desirable. In such cases a preheat of from 250-300°F. will enable the desired physical properties to be obtained.

3. **Manganese-Molybdenum Alloy Steels**—The steels in this class are alloyed with from 0.60-1.60% manganese and 0.30-0.70% molybdenum, and the carbon is usually kept below 0.25% as a maximum. These steels do not ordinarily require preheating except in certain cases where the carbon content approaches the upper end of the range. In such cases and for heavy or difficult sections, the preheating at 250-300°F. is an advantage.

4. **Carbon-Molybdenum Alloy Steels**—This class of steel is similar in many respects to the manganese-molybdenum alloys except that the manganese is held down to a normal range of from 0.30-0.60%; the molybdenum content is a little high, ranging from 0.30-1% and the carbon content is held down to the same top limit of 0.25%. Here, also, preheating is not required under ordinary conditions, although when the molybdenum approaches the upper end of the range, (above 0.50%) a preheat of 350°F. is considered desirable for best results in welding. A similar preheat is also considered desirable if the carbon content approaches or exceeds the limit of 0.25%.

5. **Nickel-Chromium Alloy Steels**—This classification embraces several analyses in which the nickel content ranges from 1% on the low side to 3½% on the high side, while the chromium ranges from 0.40% as a minimum to 1.75% as a maximum; the carbon content varies from a maximum of 0.20% for the lower tensile ranges to 0.55% for the higher tensile ranges. These steels are not capable of being safely welded without preheating. For the lower tensile ranges having a maximum of 0.20% carbon a preheat of from 200-300°F. is all that is necessary, but with the higher carbon contents that accompany the increased percentages of nickel and chromium a 600-800°F. preheat is considered desirable, followed by slow cooling. For the highest carbon, nickel, and chromium contents it is even desirable to raise the preheat temperature to 900-1100°F.

6. **Chromium-Molybdenum Alloy Steels**—These steels are similar in many respects to the preceding class. There is a much used series of alloys in this classification with the carbon range of 0.25-0.55%; molybdenum 0.15-0.25%; and the chromium 0.50-1.10%. These steels were designed especially for high temperature service and with these high chromium contents require a considerable degree of

preheat, ranging from 300-800°F., and slow cooling is desirable after the welding operation.

7. Nickel-Chromium-Molybdenum Alloy Steel—This steel contains 1½-2% nickel, 0.20-0.40% molybdenum, and 0.30-0.90% chromium. While it is an alloy that is in extensive use, it has not been welded to a sufficient extent to warrant a statement.

8. Nickel-Molybdenum Alloy Steels—In these steels the carbon content is kept low; the nickel range is 1.65-3.75%, and molybdenum from 0.20-0.30%. Welded applications have not been sufficiently frequent to furnish the desired data.

9. Chromium Alloy Steel—This steel is used in two ranges of carbon, one up to 0.25% as a max. and the other from 0.35-0.55%. With the former the chromium range is 0.60-0.90%, whereas with the latter it is 0.80-1.10%. Preheating is essential before welding. The temperature range recommended is 200-800°F.

10. Chromium-Vanadium Alloy Steel—This steel has two carbon ranges, one up to 0.25% max. and the other 0.25-0.55%. In both cases, however, the chromium is 0.80-1.10% and the vanadium 0.15-0.20%. These steels all require preheating in order to obtain satisfactory results in welding. The preheating range is 200-800°F. With this alloy sample welds may be required in order to ascertain the properties that can be obtained from the welding operation and particularly the effect of the heat-treating operation.

11. Manganese Alloy Steels—The manganese in these steels is 1.6-1.9%, carbon 0.25-0.55%. For satisfactory welding of these steels preheating is essential, the desired range being from 400-800°F.

F. Stainless Steels—The stainless alloys may be grouped into two classifications for welding considerations: (1) Stainless irons which contain from 3-28% chromium, with or without traces of nickel, and which are essentially magnetic and ferritic in character, and (2) stainless steels which contain chromium and nickel, with or without smaller amounts of molybdenum, manganese, columbium, silicon, or titanium, all of which are in such proportions as to result in an essentially austenitic phase.

1. Chromium Alloys—The alloys that come within this classification contain from 12-28% chromium as the essential alloy constituent, and are termed stainless irons. These alloys show a tendency toward grain growth in and near the weld. This tendency toward coarsening of the grain increases markedly with the chromium content and frequently results in undesirable brittleness in the welded equipment made from the higher ranges of chromium content. Small additions of nitrogen alleviate this tendency toward grain growth.

Probably the most widely used compositions for fabricated equipment come within the range of 15-18% chromium with 0.10% max. carbon. This material is readily welded and when the fabricated equipment is properly heat treated (1450°F., slowly cooled) it possesses a satisfactory combination of physical properties in both weld and plate and sufficient corrosion resistance to meet the needs of the majority of applications.

Gas Welding—Chromium irons may be welded by the oxy-acetylene method provided adequate precautions are taken, best results being obtained with a practically neutral flame. A slightly reducing flame will result in brittleness of the weld area caused by carbide formation due to affinity of chromium for carbon. A slightly oxidizing flame will result in the formation of chromium oxides, which, being refractory, sometimes results in insufficient penetration of the heat causing reduced weld strength and slag inclusions.

Arc Welding—Electric arc methods, mainly the metallic arc, are successfully used in welding stainless irons. A coated wire electrode with the metal wire of composition similar to the plate metals, with preferably slightly higher chromium, in order to provide for the metal loss during welding, is recommended.

2. Chromium-Nickel Alloys—Alloys in this classification contain sufficient nickel and manganese in addition to the chromium, with or without small amounts of other metals, to maintain an essentially austenitic condition. The composition, which probably represents the major tonnage of plates and sheets fabricated into equipment by welding, is 18% chromium, 8% nickel, and 0.10% carbon max. These chromium-nickel steels are also furnished commercially in ratios of 25-12 and 25-20, all of which have been successfully welded by methods described below.

All stainless steels, except those stabilized by columbium or titanium, when exposed to temperatures of 700-1500°F. will show an accumulation of carbides at the grain boundaries. This is known as carbide precipitation and is found in stain-

less steel that has been held in this temperature range. It is found also in lines approximately parallel to the weld bead and perhaps a quarter inch distant even in stainless plates that had been properly heat treated before welding. This is the result of the heat of the welding operation and is evidence that the plate metal in that narrow zone had been heated to a temperature range wherein carbide precipitation can take place.

This accumulation of carbides at the grain boundaries in the narrow zones adjacent to the welded bead will, in the majority of cases, show less resistance to many corrosive media than will the metal at some distance from the weld and where it had not been held in this susceptible temperature range. It is coming to be standard practice, therefore, in fabricating stainless steel vessels by welding to heat treat the equipment after completing the welding in all cases except those in which columbium or titanium is present as a stabilizing element. The heat treatment commonly used is to heat to approximately 1950°F. and quench in water. In addition to the heat treatment increasing the overall corrosion resistance of these alloys, it also puts the metal in its softest, most ductile and impact resistant form.

Gas Welding—This method is generally applied to the lighter gages. On the thinner sections, a flange type weld is used and the edges joined without the addition of welding rod. On gages where metal must be added, a bare (uncoated) rod is used with a flux added as a thin paste to the work.

The wider distribution of heat from the acetylene flame, as contrasted with the intense and local effect of the arc methods, make it desirable to use chill blocks when welding with the gas. Likewise, as a result of the more general heating and expansion of the metal sheet, since stainless steel has a 50% higher coefficient of expansion than carbon steel, it will be found convenient to use jigs and clamps to hold the work.

It is of paramount importance in gas welding stainless steel to adjust the flame so that it is practically neutral. This will avoid excessive carbon pick up in the metal which would materially reduce the corrosion resistance of the resultant weld.

Arc Welding—The usual methods of arc welding are successfully applied to joining the stainless steels. Altogether satisfactory electric welding is done using direct current in preference to alternating current. Reversed polarity, that is, work negative and electrode positive, is normally used. Coated metallic electrodes are preferred. The composition of the welding wire should be similar to the composition of the plate, preferably with the chromium in the wire slightly higher.

As pointed out previously, austenitic steels are susceptible to grain growth at high temperature. Overheating is, therefore, to be avoided. Adjust the current quality to give smooth arc and proceed with laying down the bead as rapidly as is consistent with good welding practice.

G. Copper and Copper Alloys—1. Copper, Tough Pitch, Electrolytic and Lake—The materials of this group have high thermal conductivity and a tendency toward oxide embrittlement which are the chief obstacles to welding them. The high thermal conductivity requires an unusually high input of heat in the welding zone in order to compensate for the loss of heat to the surrounding metal. The cuprous oxide in the base metal adjacent to the weld is reduced by the hot hydrogen gas or tends to collect at the grain boundaries causing a material reduction in weld strength which may, however, be corrected by hot forging.

Resistance Welding—The resistance welding of this material has been unsuccessful commercially on account of its high thermal and electrical conductivity. Resistance brazing is possible by use of carbon resistor electrodes. Resistance flash butt welds are commercially possible on copper wire and rods with a special procedure.

Gas Welding—These materials can be gas welded with a sufficiently large flame or by preheating with a charcoal fire or with some form of preheating torch. The work should be insulated for heat conservation as well as for comfort of the welding operator. The back hand method of welding is preferable for thicknesses greater than $\frac{1}{4}$ in. If the full strength of the annealed metal is desired, it is necessary to hot forge the weld or cold peen and anneal it.

Arc Welding—These materials can be readily welded by the carbon arc, using a phosphor bronze or silicon-copper filler rod. The metallic arc is sometimes used for sheets $\frac{1}{8}$ - $\frac{1}{2}$ in. in thickness, but is unsatisfactory for thicker sheets. It is generally necessary to do flat welding though under certain conditions some position welding can be done with the carbon arc and a silicon-copper filler rod.

2. Deoxidized Copper—This material is a decidedly easier metal to weld than is the oxygen-bearing copper and it should be used in all cases where the equipment

to be welded is to be subjected to severe service. It is not subject to hydrogen embrittlement and, though its thermal conductivity is somewhat lower than that of tough pitch copper, this property is still high enough to call for a high input of welding heat.

Resistance Welding—This material is nearly as difficult to resistance spot and seam weld as the preceding material. Where necessary to resistance spot and seam weld, a satisfactory connection can be made by inserting thin phosphor bronze strips or coating the surfaces with tin or solder.

Gas Welding—The procedure for gas welding of this material is much the same as that for the materials of the preceding group. Hot forging of the weld or cold hammering followed by an anneal will improve the ductility and strength, but the material is generally used in the as-welded condition.

Arc Welding—The procedure for arc welding of this material is quite similar to that for the materials of the preceding group, but it is difficult to weld this material in thicknesses greater than $\frac{1}{4}$ in. by the metallic arc process. With the carbon arc process satisfactory results can be obtained.

Bronze Welding—Bronze welding of this material has proven particularly satisfactory in connection with copper tube and brass pipe plumbing installations.

3. Commercial Bronze, Red Brass, Low Brass, Ounce Metal, and Hydraulic Bronze—These constitute some of the most common commercial alloys of copper and are usually encountered in the form of sheets, tubes and wire. The leaded alloys are largely used as castings for pipe fittings, or valve bodies. The group is, in general, quite weldable except that, if the weld metal is superheated, trouble is experienced with zinc vaporization. The unstable lead oxides sometimes weaken the welds made in the leaded alloys.

Resistance Welding—Resistance, spot and seam welding of this group of materials is almost as difficult as on copper, because in addition to the high electrical and thermal conductivity there is danger of zinc vaporization.

Gas Welding—The procedure for this class of material is similar to that for the two preceding groups. Where for artistic purposes an exact color match is desired it is usually necessary to use strips of the base metal for filler metal. A strongly oxidizing flame is sometimes used to suppress zinc vaporization. A good brazing flux is always required.

Arc Welding—The arc welding of materials in this group is difficult except where the carbon arc can be played on a zinc-free filler metal as applied in flat butt or lap welding so that the base metal is not fused but is heated by the highly superheated weld metal. This is the only manner in which serious difficulty from zinc vaporization can be avoided.

Bronze Welding—This material can be readily bronze welded provided a satisfactory flux is used.

4. Brazing, Spring, Admiralty, Commercial, Alpha, and Yellow Brass—These more common of the brass alloys have a sufficiently low melting range and heat conductivity to render oxy-acetylene and resistance welding comparatively easy. They are not, however, as easy to weld by the electric arc method as the materials in the preceding group and the use of metallic arc welding is not recommended for any application on account of the vaporization of the zinc. A brazing flux is used invariably on this group of alloys.

Resistance Welding—Resistance welding can be applied to this group of materials by machines that have carefully controlled pressures and current timing. The material must be carefully cleaned and prepared as any unexpected change in conditions may cause burning of the work or of the electrode.

Gas Welding—While the gas welding process is considered the most satisfactory method for welding these alloys, the temperature of the gas flame is high enough to render rapid vaporization of the zinc unless care is taken to avoid it by either controlling the heat of the flame in the application or by using a strongly oxidizing flame. Special fluxes are also used for the purpose of covering the molten weld metal with a suitable film to suppress zinc vaporization and obtain sound weld metal.

Arc Welding—While metallic arc welding is generally unsatisfactory for this group of alloys, it is possible to apply carbon arc welding by a suitable technique in which the arc is directed toward the zinc-free filler metal rods.

5. Muntz Metal, Tobin Bronze, Naval Brass, Manganese Bronze, and Extruded Brass—The materials in this group are similar in welding properties to the yellow brass group. They have good hot forging and extruding qualities and also have high strength and good corrosion resistance.

Resistance Welding—This material can be resistance, spot and seam welded quite satisfactorily. The current values are about the same as those required for steel. The pressure exerted on the work should be light and the balance of application of heat should be as short as possible.

Gas Welding—Oxy-acetylene welds in this material are strictly fusion welds, although the heat conductivity of the material is still high as compared with that of steel, so that a large flame is necessary. Zinc vaporization is suppressed by using an oxidizing flame. Where used in the form of architectural bronze a good color match is obtainable in welding if filler metal strips are cut from the base metal.

Arc Welding—These materials are not commonly welded by the metallic arc process, but welds are possible by use of the carbon arc method using a long arc. They are not ordinarily welded in thicknesses exceeding $\frac{1}{8}$ in.

6. Nickel Silver—This group of materials is used where a white metal or artistic metal is desired and to some extent for reason of corrosion resistance. The nickel content renders the material easier to weld on account of the lower thermal and electrical conductivity. There is a tendency for nickel oxide to form but this can be checked to some extent by the use of a suitable flux.

Gas Welding—The oxy-acetylene process is well adapted for the welding of this material, particularly in connection with certain lapped connections. Nickel silver welding rod is given the preference because it makes a good color match with this material. This material is largely used in architectural designs and is particularly well adapted for butt or mitered joints. One of the essentials for applying gas welding to this material is that both the base metal and the welding rod must be cleaned and covered with a good brazing flux, and a neutral flame should be used.

Arc Welding—Carbon arc welds can be made satisfactorily if phosphor bronze electrodes are used, although silicon-copper electrodes should be used where it is necessary to perform position welding. In case of metallic arc welding covered electrodes are necessary to obtain satisfactory strength and color match. With this process difficulty is experienced with vaporization of zinc from the base metal.

7. Phosphor Bronze—Most of these alloys have insufficient phosphorus to insure thorough deoxidation and as a result tin oxide and in some cases lead oxide are likely to be developed in the weld metal. This should be avoided by keeping the heat, in the case of arc welding, off the base metal and playing it on the weld metal which should have sufficient phosphorus to insure deoxidation. The metal is inclined to be hot short and subject to dendritic shrinkage cracks under certain conditions. For instance, a wide spreading heat and slow cooling are likely to produce these hot short cracks and porous places in the weld metal. A narrow heat zone with quick solidification promotes soundness.

Resistance Welding—This process of welding is applicable only to this group of metals in sheet and wire free from lead. It welds at a lower heat and at about the same pressure as brass, and strong sound welds are the usual result.

Gas Welding—On account of slow cooling and high shrinkage this process of welding is not so desirable as some of the others. Welds of this process must necessarily be fusion welds if phosphor bronze welding rods are used, but the base metal need not be fused if the rods are of yellow bronze. The latter do not give a good color match but this yellow bronze is the easiest metal to apply without danger of developing hot short cracks. With either metal a neutral flame and a good brazing flux are desirable. If a phosphor bronze rod or cast bronze rod with a high percentage of tin is to be used, a reasonable degree of preheat is necessary.

Arc Welding—Arc welding is satisfactorily applied to this group of materials. With the carbon arc process, the arc should be played on the weld metal so as to avoid oxidation of the tin in the base metal. With this process the concentrated application of heat tends to keep the contraction at a minimum. The use of a flux is desirable although not entirely necessary. Welds of this type can be made only in the flat or nearly flat position. If the metallic arc process is to be used a flux coated phosphor bronze electrode is to be preferred to the bare electrode in order to reduce the tendency toward oxidation of the tin.

8. Copper-Silicon Alloys—These copper-silicon alloys, although commonly carrying about 96% of copper, have low heat conductivity and develop a continuous protective film on the metal the instant it is melted. This film helps to hold the metal in place in fusion welding. Rapid solidification and cooling are desirable in order to keep the grain size small. Considerable care must be taken in the welding of this material to insure a fine grain structure which results in suitable tensile

strength and ductility. The work for welding this material is usually set up in jigs so as to hold the edges rigid. The welds in these alloys are improved in both tensile strength and ductility by peening and annealing, the peening to be done when the metal is cold or nearly cold.

Resistance Welding—The materials in this group are well adapted to resistance, spot and seam welding. The current values are somewhat greater than those required for the same thicknesses in steel and the pressures required are less. A short heat-on period is desirable as the metal is very fluid at the interfaces.

Gas Welding—With this process the flame should carry a slight excess of oxygen which tends to protect the weld metal by an impervious film of the molten silica. It is important that the base metal shall be fused simultaneously with the welding rod in order to avoid incomplete fusion or laps.

Arc Welding—This process has the advantage of highly localized heat but on account of the high fluidity of the weld metal, the work must be welded in the flat position. The carbon arc method is given preference by some operators because of its ease of control. This process is possible to some extent with position welding. The metal should be clean and covered with a suitable flux.

9. Cupro Nickel—These alloys are well adapted to fusion welding. The four sources of trouble to be overcome are: (1) The refractory unfluxable nickel oxide which causes the metal to solidify with a rough surface; (2) the tendency of the metal to absorb gas when molten and reject it when solidifying, which causes porosity; (3) the tendency toward red shortness; and (4) the danger of burning out the protective deoxidizers.

Resistance Welding—The materials in this group are readily welded by the resistance process, being rated as among the best of the copper alloys for this group.

Gas Welding—These materials can be welded by the gas welding process provided the welding rod has sufficient deoxidizer and a soft flame is used so as to allow quick solidification with minimum agitation. The weld metal will be covered with a silicon film and the weld should be kept running continuously until completed.

Arc Welding—With metallic arc welding a heavy flux coating on the electrodes is essential for sound strong welds. The carbon arc method of welding has not been applied to this material.

10. Aluminum Bronze—These alloys are, as a rule, harder and more readily forgeable than the alpha brasses. They may be bronze welded, but care should be exercised to start with a clean base metal and cover same with flux before the heat is applied.

Gas Welding—If the aluminum content does not exceed 5% the material can be readily welded by the gas welding process, using a suitable flux. The welding rod must be of correct size so that it will melt only as fast as it is puddled into the weld. The torch adjustment should, for this material, be slightly reducing.

Arc Welding—A long carbon arc constitutes the most effective method of welding the materials in this group. It forms a straight fusion weld and the deposit is enhanced by a suitable flux covering. The work should be set up so that the weld is made in as nearly as possible the flat position. The metallic arc process has not been satisfactorily applied to the materials in this group.

11. Beryllium Copper—This material is susceptible to heat treatment and will attain its maximum strength and hardness with a final precipitation heat. Therefore, the reduction of strength at the region of the weld can be greatly improved by subsequent heat treatment in that zone. This may be accomplished either by hot rolling or forging or by a homogenizing anneal. The usual brazing flux will not dissolve beryllium oxide but will tend to prevent this oxide film from forming.

Resistance Welding—The materials in this group are readily resistance, spot and seam welded using relatively light pressure and short heat-on periods.

Gas Welding—Thus far no flux or gas fusion welding procedure has been discovered which will eliminate the difficulty arising from the refractory insoluble film of beryllium oxide.

Arc Welding—The carbon arc process is considered the most satisfactory for welding this material because it is possible with a short arc and a high heat to have the weld metal flow into the base metal before the tough oxide film is formed. A thin application of flux is desirable but not essential. As the metal is extremely fluid only welding in the flat position can be performed and a copper backing-up strip is essential.

H. Aluminum and Aluminum Alloys*—The common welding methods which have been adapted to joining aluminum and the aluminum alloys, include gas, atomic hydrogen, metallic or carbon arc, and resistance welding. In each case some knowledge of the metallurgical and physical characteristics of the aluminum alloys must be considered to obtain economical results and sound joints. In the following is included a general discussion of the essential characteristics of each welding method as applied to all of these alloys.

Gas Welding (General)—The commonly used gases for welding aluminum and its alloys are oxy-hydrogen and oxy-acetylene. Equally good results from the standpoint of soundness, strength, speed and appearance are obtained with either gas. Standard equipment in the way of torches, hose and regulators are suitable for welding such materials. Some work has also been accomplished with oxy-natural gas and oxy-propane derivatives, and while good soundness and strength have been obtained in such welds, the use of these gases does not appear to be economical because of the comparatively low rate of welding.

When fusion welding aluminum, it is important that a suitable flux be used to remove the oxide coating which forms on the surface of all aluminum alloys in the atmosphere. This oxide coating does not melt at the welding temperatures and will prevent smooth coalescence of the weld metal unless a flux is provided that will melt somewhat below the welding temperatures and which breaks down the surface skin of oxide permitting the liquid metal from the rod to flow into the molten parent material. A number of good fluxes are available. These are applied either dry or by mixing with tap water to the consistency of a thick paste.

Practically all aluminum welding fluxes contain chlorides, fluorides, and sulphates. Residual deposits on the joints after welding will, in the presence of moisture, attack the base metal. Thorough cleaning is especially necessary on parts that are to be painted, as the presence of flux will lift the paint coatings over the welds. Such action can be prevented by cleaning the parts after welding by scrubbing the joints in boiling water. On tanks or parts where the joints are inaccessible, neutralization of the flux can also be accomplished by dipping for 30 min. in a 10% solution of cold sulphuric acid, or a 10 min. immersion in a 5% solution of sulphuric acid held at 150°F.

The proper choice of filler material for gas and atomic hydrogen welding is important, particularly when joining alloys with comparatively large amounts of alloying constituent. Commercially pure aluminum and metal of higher purity are generally welded with the same grade of metal as the parent material. The same practice is satisfactory for the aluminum-manganese alloys. In welding the aluminum-magnesium alloys or the aluminum-silicon-magnesium alloys, a filler rod containing 95% aluminum and 5% silicon is generally used. This rod has a substantially lower melting point than pure aluminum, and permits the dissipation of some of the stress set up by solidification shrinkage and the thermal contraction which occurs in the weld zone as it cools. Cracks in the weld and the transition zone, on parts that are welded in jigs to hold proper alignment, can be minimized by using this rod.

Arc Welding (General)—Aluminum and its alloys can be fusion welded with the metallic arc or the atomic hydrogen process. These processes have the advantage that the highly concentrated heated zone obtained with the arc prevents excessive expansion of the parts being welded with consequent lessening of distortion. In addition, the preparation of the joints for welding is simpler and the rate of welding is faster.

Because of the relative difficulty of controlling the arc, it is ordinarily not practical to butt weld material lighter than 0.06-0.08 in. thick or fillet weld joints on plate much lighter than $\frac{1}{8}$ in. thick. The soundness of the welds, particularly in thin material, is usually not equal to that of gas welds. While arc welded joints are equal in strength to gas welded joints, it requires considerable care to obtain liquid or gas tight joints in material lighter than $\frac{1}{8}$ in. thick.

Metallic arc welds can be satisfactorily made with direct current, but the proper polarity to be used should be determined by trial on the joints to be made. The capacity of the equipment and the electrode size are determined by the thickness of the material to be welded. Electrodes $\frac{1}{8}$ in. in dia. can be used on thicknesses ranging from 0.064-0.125 in. material, using amperages from 45-85; $\frac{3}{16}$ in. electrodes are suitable for thicknesses from $\frac{1}{8}$ - $\frac{1}{4}$ in. for which amperages of 85-175 will be required; for $\frac{1}{4}$ in. thickness a $\frac{1}{4}$ in. electrode and amperages from 175-225 will be

*By G. O. Hoglund, Welding Engineer, Aluminum Co. of America, New Kensington, Pa.

required, while for $\frac{3}{8}$ in. thickness, a $\frac{1}{4}$ in. electrode should be used with an amperage from 225-300. In general, the use of heavy currents at high welding speeds is helpful.

Unless a suitable flux is provided, the oxide coating present on the filler rod and the parent material will prevent coalescence of the weld metal. Consequently, successful results are most easily obtained by using a coated electrode on which a heavy coating is provided that functions both to remove the coating on the metal, and to stabilize the arc. As the aluminum-silicon alloy provides superior fluidity at the welding temperatures, it is used for the filler material in all of the commercially available electrodes.

When the atomic hydrogen process is used, a good grade of aluminum flux should be used. A number are available, and, as a general rule, when mixed with water to the consistency of a thin paste should be applied to both the filler rod and the seam.

As in gas welding, the choice of filler material is important with this process and follows the same rules. Where the thickness of metal being welded is sufficient to allow the manipulation, the filler rod may be inserted in the molten pool and moved back and forth to assist in breaking up the oxide film which is present. As aluminum flows readily after reaching the molten state, care must be used to keep the molten metal from falling through. To prevent this, particularly on plates heavier than $\frac{1}{8}$ in., it is desirable to back up the weld.

Cracking can be largely avoided with atomic hydrogen welding by making a short weld about an inch long at the beginning of a seam and allowing it to cool before proceeding with the remainder of the seam. Castings should be preheated to approximately 425°F. before welding and allowed to cool slowly after the weld is completed. Sawdust sprinkled near the seam will char at about the correct preheating temperature. A powdery layer of oxide and flux gradually accumulates on the electrode clamps and may cause the arc to flow between the electrode holder tips instead of between electrodes, with resulting damage to the tips. If the ends of the electrode clamps are dipped in water occasionally, this accumulation will be dissolved.

Resistance Welding (General)—The aluminum alloys are joined in production by spot, seam, and push or flash welding methods. Sound resistance welded joints can be made provided proper welding equipment is used; the surface of the metal is prepared correctly and the proper machine settings are used in operating the equipment.

Equipment characteristics for spot welding aluminum are not basically different from those used for welding other metals, except more rigid control of time and pressure is desirable and integration of current should be done in smaller steps. In considering timing, electronic equipment that insures delivery of a definite number of cycles, and eliminates undesirable transients in the secondary circuit by making and breaking the current at the zero point on the a.c. current wave, gives best results, particularly on light gage material. Good results can also be obtained with contactor type timers, controlled either mechanically or electronically. Experience has shown also that hydraulic or pneumatic pressure mechanisms are superior for spot welding the aluminum alloys in that duplication of pressure at the tips can be obtained most accurately. Current in the secondary circuit must be relatively high in equipment for spot welding the aluminum alloys because of the high thermal and electrical conductivity of these materials. This factor is a question of machine design which should be considered in machine specifications in order that sufficient current is available.

Preparation of the surface of the material is significant, particularly from the standpoint of welding cost. The oxide coating on some alloys is sufficiently resistant to passage of the welding current to cause surface heating, with consequent alloying of the welding tip materials with the parts. This is particularly true of the heat treated alloys where the thermal operations required in heat treating increase the thickness, and consequently the resistance of the surface oxide coatings. It is desirable on those alloys where excessive tip wear occurs, to remove the oxide coating prior to welding. This can be done mechanically with steel wool or emery cloth, or with a chemical etch.

It is essential in setting up a welding operation to use welding tips that will maintain consistent current and pressure distribution during successive welds. The common method of dressing tips with a file is not suitable for spot welding the aluminum alloys. Good results in practice have been obtained by machining a contour on the tip that can be maintained periodically with a fine grade of emery held

in the fingers. A tip machined to a cone 158-165° included angle, or a tip with a hemispherical end is usually used. Spot welding tip materials should have a conductivity better than 75%, and a hardness exceeding Rockwell B 60. Calibration of the current and pressure delivered by a machine are essential to make proper machine settings.

Seam welding is a special application of spot welding in which rolls are used for electrodes, and the current is applied intermittently. Machine characteristics, as outlined above, apply as well to seam welding equipment except that successful results have been obtained only with electronic timing devices. In making liquid or gas tight joints, the timing cycle is adjusted so that the current is on not more than 30% of the time. By adjusting the timing cycle and the speed of the rolls, overlapping or intermittent welds can be made. Machine settings for seam welding depend upon the gage, temper, and alloy to be welded, and specific problems in connection with supplying suitable equipment should be referred to the machine manufacturers.

The electric butt resistance welding of all the wrought aluminum alloys is possible if a welder of proper design is available, but the aluminum-manganese and high purity aluminum are more readily welded by this method.

Simple cylindrical and rectangular sections of aluminum can be push welded. The parts to be welded are clamped in dies and pressure is applied before the application of power. Application of power causes surface melting of the aluminum and softening of the metal near the plane of contact. The joint is held under pressure by the dies, which causes the molten and soft metal to squeeze out of the joint. Power is cut off after a predetermined die travel or number of cycles of current application. Rapid freezing of the weld takes place because of conduction of heat away from the joint.

Push welds require excellent fit between the pieces being welded and between the pieces and the clamping dies. Equipment for such welding is characterized by high current capacity and rapid free movement of the movable die.

The flash butt weld process is adaptable to welding complicated extruded shapes of aluminum as well as the simpler cylindrical and rectangular shapes. The parts to be welded are clamped in dies and power is applied before the parts are allowed to come in contact. Movement of the dies together is accomplished by a motor driven cam which imparts an accelerated motion to the movable die. Flashing is maintained for from $\frac{1}{2}$ -1½ sec. during which time from $\frac{1}{2}$ -1 in. of aluminum is flashed from the parts being welded. The flashing period is terminated by the nearly simultaneous cutting off of power and a sudden increase in velocity of the moving die. The ends of the parts being welded are forced together and rapid freezing of the weld takes place because of conduction of heat to the dies.

Good fit between the parts being welded is not necessary. Dies should fit the aluminum section well enough to provide mechanical support for projections or thin sections and clamping pressure must be high enough to prevent slippage during the final push-up period.

The relation between welding time, die motion, die spacing and welding current is varied for each section and alloy of aluminum welded. Sufficient data on machine settings are not available, and for this reason it is recommended that before obtaining equipment for flash welding aluminum, tests on the particular alloy and section be made to determine the electrical and mechanical specifications for a suitable machine.

1. High Purity Aluminum—In some cases it is necessary to use material of purity higher than commercially pure aluminum, in order to obtain better resistance to certain types of chemical attack. A typical example is found in storage or fermenting tanks used in the brewery industry where a purity of 99.5% aluminum is usually applied.

Resistance Welding—These materials lend themselves readily to spot, seam or butt welding and no special practices are required. The resistance to corrosion of resistance welds is not inferior to the parent material.

Some difficulty may be experienced in attempting to spot or seam weld high purity aluminum in the soft temper on material that is heavier than 0.100 in. thick. This is apparently caused by the fact that the hardness of these materials in the soft temper is not sufficient to prevent the welding electrodes from deforming the surface, with consequent spreading of the current and pressure distribution during the welding cycle. This results in weak and inconsistent welds. This is not true in the intermediate or hard tempers of these materials.

Gas and Arc Welding—High purity aluminum requires no special treatment from the standpoint of welding technique when considering equipment, preparation of joints, or machine settings. In order to obtain comparable resistance to corrosion in the welds to that in the parent material, a filler wire of the same composition as the parent material should be used. This is frequently handled by shearing strips from the parent material. If metallic or carbon arc welded joints are to be made in these materials, special flux coated electrodes with a filler material of high purity wire should be obtained.

Welds in these materials are characterized by comparatively high ductility and dressing operations are usually carried out by hammering. A tensile strength across the welds equal to the strength of the annealed temper of the parent material is obtained on fusion welded joints regardless of the temper of the material prior to welding. Sound welded joints can be made in any of the commercial forms of these materials.

2. Commercially Pure Aluminum—Commercially pure aluminum is readily weldable by all methods. It is widely used on dairy and chemical tankage wherever the mechanical properties are adequate.

Resistance Welding—All of the commercial forms of commercially pure aluminum are spot, seam, or butt welded in production. No special technique is required for welding these materials and because of the excellent surface present on commercially pure aluminum, this is probably the most economical alloy to use from the standpoint of resistance welding cost. It is also common practice to resistance weld cast parts in which the composition has been varied to improve mechanical properties or casting qualities to articles made from commercially pure aluminum.

The previous remarks concerning the welding characteristics of the annealed temper mentioned in Section 1, apply as well to commercially pure aluminum, though to a lesser extent.

Gas and Arc Welding—This material can be both gas and arc welded, and commercial applications have been made on parts ranging in thickness from 0.020-1 in. Butt welds are characterized by high ductility in the welds and excellent resistance to impact or shock loading. A strength equal to the tensile strength of the annealed material is obtained in the welds.

Commercially pure aluminum is generally used as a filler material when making welds and considerable testing and practical use has indicated that the resistance to corrosion of such welds is substantially equal to that of the parent material. Metallic arc welding is generally done with standard flux coated electrodes containing Al-Si filler rod. However, where maximum resistance to chemical attack is important, a special coated electrode containing commercially pure aluminum filler material should be used.

3. Al-Mn Alloy—This alloy is substantially the same as commercially pure aluminum from the welding standpoint, except that the mechanical properties of both the parent material and of welded joints are higher.

Resistance Welding—In this case also, no difference is apparent in the technique of welding this alloy compared to commercially pure aluminum. The strength of the welds, however, is higher.

Gas and Arc Welding—This alloy is widely used where higher strength than can be obtained in welded parts made from commercially pure aluminum is required. The previous remarks on filler wire and resistance to corrosion apply as well to this material.

4. Al-Mg-Cr Alloy—By alloying aluminum with magnesium and chromium, a material is available with considerably higher mechanical properties than can be obtained with the previously mentioned alloys. This introduces some problems, particularly from the standpoint of fusion welding, which are described in the following.

Resistance Welding—This alloy can be readily spot, seam or butt welded and because of the high strength and hardness, no difficulty is experienced with any temper. Some of the commercial forms, particularly the annealed sheet, are covered with an oxide coating that will cause wear on the welding electrodes unless it is removed prior to the welding by mechanical or chemical means. The strength of spot and seam welds in this alloy is higher than that obtained with the previously mentioned materials. Spot welding this alloy has found wide application for assembling airplane gasoline tanks.

Gas Welding—This material is more sensitive to the application of the welding heat in that cooling cracks, caused by the thermal contraction and solidification shrinkage may occur when the weld cools. This condition is minimized if a filler

material of lower melting point than the parent material is used, and practically all gas welding is done with an Al-Si filler rod. The above condition is not serious when the thickness of the parts is such that welds can be made in one pass. Consequently, most commercial applications have been made on material up to $\frac{1}{4}$ in. thick. Welded joints in thicker parts will usually require some preliminary trial to determine a method that will cause the least stress in the welds during the cooling period.

The strength of welds in this alloy is generally equal to the strength of the annealed material, but the elongation in the welds is substantially lower than that obtained on commercially pure aluminum or the Al-Mn alloy.

Arc Welding—The above remarks do not apply to joints made with the metallic or carbon arc welding processes. In this case the welding heat can be concentrated to a narrow zone and the difficulties from cracking as the weld cools are practically eliminated. The standard arc welding technique using Al-Si filler wire in the electrodes is generally used for arc welding this alloy.

5. Al-Mg-Mn Alloy—This alloy is similar, from the welding standpoint, to Al-Mg-Cr alloy just described, and the welding characteristics as described can be applied in this case.

6. Al-Si-Mg Alloys—These alloys rely for their strength on heat treatment operations in which the material is treated thermally so that the metallurgical structure is arranged to obtain comparatively high mechanical properties. It follows that the application of welding heat may partially obliterate the heat treated structure with consequent lowering of properties.

Resistance Welding—These alloys are widely used for resistance welding applications, particularly of the type where structural sections are spot welded to sheet panels to stiffen the panels.

Because of the heat treating operations applied to these alloys, an oxide coating is usually present on the surface which interferes with the passage of the welding current. In order to prevent surface heating between the parts and the welding tips, mechanical or chemical cleaning operations are performed on the surface contacting the welding tips prior to welding.

Gas Welding—All of these alloys can be joined with the welding torch. A width, in the parent material, from two to five times the thickness of the material has been effected by the heat in this method of welding. Reheating after welding will increase the strength of the joint, but because of the cast structure in the weld, a strength equal to the parent material is not obtained. The strength of a gas welded object of these alloys is usually not predictable as the annealing effect of the welding heat is dependent on the amount and location of the welds in the parts. Mechanical tests on the welded parts are usually carried out to determine the suitability of the welded assembly for the service intended.

The welding technique is substantially the same as for other materials and the resistance to corrosion of welded joints is good. Filler wire of Al-Si is usually used.

Arc Welding—Because of the comparatively narrow zone affected by the welding heat, less difficulty is experienced from cooling cracks when these alloys are assembled with the metallic or carbon arc. The strength of the welds, however, is approximately the same as that obtained with the gas torch and the previous remarks made in connection with gas welding apply as well to arc welded joints. Flux coated electrodes containing Al-Si filler wire are used for arc welding these alloys.

7. Al-Cu-Mg-Mn Alloys—This group of materials contains the aluminum alloys in which the strength is increased to a maximum by heat treatment operations. The effect of welding operations is, with two exceptions, to reduce the resistance to corrosion and mechanical strength. Consequently, these materials do not find extensive use in welded parts.

Resistance Welding—These alloys can be assembled by spot, seam or butt welding with good results, from the standpoint of static mechanical strength. Exposure tests on resistance welds have indicated that the resistance to corrosion of the welds is not equal to that of the parent material. Protection by paint is essential to insure lack of deterioration in the joints from corrosion. It is important in some applications, particularly aircraft structures, that the resistance to corrosion of spot welds be as good as the parent material in the high strength alloys. This is obtained by providing a surface on the alloys of high purity aluminum that protects the material from corrosive influence. For this purpose aluminum clad materials have been produced and considerable testing of spot welds exposed to corrosive

conditions has indicated that welds can be made in these alloys that have corrosion resistance equal to the parent material.

Gas Welding—Both the strength and resistance to corrosion of welds in these alloys are substantially lowered by gas welding.

Arc Welding—The previous remarks on gas welding apply to metallic and carbon arc welding of these alloys. However, when the welds can be placed in the structure where the stresses are low, these alloys can be arc welded. As the welding heat may affect the structure of the alloy, it is suggested that welded parts be tested prior to use.

I. Nickel and Nickel Alloys*—Nickel and the high nickel alloys are welded by the methods commonly used for the joining of steel (oxy-acetylene, metallic arc, carbon arc, resistance welding, and flash welding methods).

1. Rolled Nickel—Resistance Welding—The spot, seam or stitch and projection welding of this material is readily done. One practical application of the spot welding of nickel is the internals of radio tubes.

Gas Welding—This material is readily gas welded using the oxy-acetylene flame. The filler metal should be a bare nickel gas welding rod made for the gas welding of wrought nickel, and with which no flux is used or needed. The oxy-acetylene flame should be slightly reducing with a $\frac{1}{8}$ in. excess acetylene feather. The envelope of the flame serves to preheat the unwelded seam (forehand welding), with the welding rod kept within the flame envelope to avoid undue oxidation of the heated end of the rod. It is not necessary topeen the gas weld when it is either hot or cold, as there is no porosity present. Certain types of fabricators still prefer to cold work welded equipment—a procedure which is not harmful if care is taken to avoid excessive cold work. The deposited metal is extremely ductile and can be cold worked in later forming operations.

Arc Welding—A nickel welding electrode with a heavy flux to protect the weld metal as it passes from the electrode through the arc to the plate being welded is required. No flux other than that on the electrode is necessary. Nickel is satisfactorily welded using reversed polarity, that is, with the electrode positive and sheet negative, and with a short arc—24-26 volts across the arc. Welding can be done in any position—the flat or downhand, vertical or overhead positions. Tensile strengths of arc welded butt joints in nickel are of the order of 60,000 psi. min. with satisfactory ductility.

Carbon Arc Welding—A small dia. carbon, $\frac{1}{8}$, $\frac{3}{16}$, or $\frac{1}{4}$ in. in dia., tapered about 2 in. to a pencil point is used on straight polarity with a short arc. The carbon arc merely supplies the heat and is either used to fuse together edges or is used with a lightly fluxed nickel filler rod.

Silver Brazing—Silver brazing is easily done using the low temperature brazing alloys and appropriate silver brazing fluxes. The use of borax as a flux is to be avoided as it affords insufficient protection, while the low flow point solders are melting.

2. 67% Ni-30% Cu Alloy—Resistance Welding—With spot, seam, stitch or projection welding, high current densities flowing for short times, less than 15 or 20 cycles, are preferred. Pressure should be just sufficient to hold the metals in contact to prevent arcing or undue spatter.

Gas Welding—The gas welding of this alloy is done with a gas welding wire of the same composition and a gas welding and brazing flux designed for this alloy. A slightly reducing flame is required as with nickel and under this flame the weld metal is very fluid. Position welding is regularly done on pipe lines. The pool of molten metal is not to be puddled or boiled as this may introduce harmful oxides which in turn may embrittle the weld.

Metallic Arc Welding—The electrode for the metallic arc welding of wrought and cast forms of this alloy consists of a wire with a core of the same composition as the alloy with a heavy flux covering.

Reversed polarity with the electrode positive and the plate negative is required for welding in the downhand, vertical, or overhead positions. Regardless of the position of the work, the electrode is held approximately normal to either the plate or the surface of the pool of molten metal.

Tensile strengths are of the order of 70,000 psi. min. and elongation in free bend 30% minimum, with nick break tests, and X-ray examinations satisfactory.

Carbon Arc Welding—A small dia. carbon pencil, $\frac{1}{4}$ in. or smaller, is ground to a long taper and gripped in the electrode holder in a straight polarity welding

*By Frank Flocke, International Nickel Co., New York.

arrangement. A welding rod of the same alloy with a light coat can be used where filler metal must be added to the joint. In other cases, the carbon pencil may be used to make an edge weld by melting the flanged edges of sheet metal, in which case no filler rod is added. This joining method is particularly useful for melting down the ends of thin walled tubes projecting beyond the surface of tube sheets or in welding this alloy of the order of 0.050 in. or 0.062 in. in thickness where a minimum of finishing is required.

3. 79% Ni-13% Cr-6% Fe Alloy—Resistance Welding—The notes in the section above on the resistance welding of the 67-30 Ni-Cu alloy apply equally in the present case of joining this Ni-Cr-Fe alloy.

Gas Welding—A welding rod of the same composition as the material being welded should be used. Since the oxides of chromium are refractory and tend to interfere with gas welding if not fluxed away, a flux suitable for chromium bearing nickel alloys will be found useful. Sound, ductile welds are easily made with a moderately reducing oxy-acetylene flame and appropriate welding rod and flux.

Metallic Arc Welding—An electrode of the same alloy with a suitable flux coating is used in making arc welded joints. This alloy is regularly welded using reversed polarity. Welds are strong and ductile.

4. Ni-Cu-Al Alloy—Resistance Welding—The information given above on the resistance welding of the Ni-Cu alloy applies equally to the spot and seam welding of this Ni-Cu-Al alloy.

Gas Welding—The use of a special flux applied in the form of a water paste is required to produce sound gas welds. The heated end of the filler rod of the same alloy must be kept within the protecting envelope of the oxy-acetylene flame to prevent oxidation of the aluminum constituent of the rod. A strongly reducing flame is required.

Metallic Arc Welding—As this is a nonmagnetic, heat treatable alloy, welds made in this material must have similar characteristics, thus necessitating the use of a coated electrode of the same alloy. Metallic arc welds can be annealed or hardened by heat treatment.

Silver Soldering—Care must be taken when preparing this alloy for silver soldering to have all edges smooth to avoid any sharp notches, or cracking will result because of the hardness of the metal. A low temperature silver brazing alloy melting about 1175°F. is preferred.

J. Lead—Jointures in lead have been made for many years by a process known as lead "burning" for sheets and plates, and lead "wiping" for pipes and irregular sections. The term "lead burning" is, however, a misnomer, as the lead is not burned but is fusion welded by application of a suitable flame, either with or without the addition of filler metal.

Lead is a material of high density but low melting point (621.3°F.) in its commercial forms. By alloying with antimony, bismuth, cadmium or tin, its physical properties can be greatly changed, including the melting point. Due to its relatively low range of melting temperatures, it is difficult to manipulate under the welding flame, and if the operator is not careful it is only too easy to burn holes through the material being joined.

Two forms of joints are used with sheet lead, the butt and the lap types. With the butt type the edges of the plate do not need to be beveled unless the plate is of considerable thickness, in which case the edges are beveled to an included angle of about 30°. The edges of the plates to be welded are scraped clean and bright on both sides to remove all lead oxide for a distance of about ½ in. back from the edges. This is usually accomplished by use of a sharp shave hook. For welding the edges are placed close together, then tacked at points about 1 ft. apart and the V is filled in with molten lead fused with the flame from the end of a lead filler rod. The seam is usually filled in with lead to give some reinforcement, particularly on heavy plates.

In making lap joints the edges are cleaned of lead oxide on both sides for a width considerably more than the width of overlap, using a sharp shave hook. The sheets are lapped from ½-1½ in. according to the thickness of the plate and the strength of the joint that is required. The welding flame is used to fuse the plates by melting out a section of the upper sheet edge which flows down and joins into the lower sheet. The flame is carried forward by a succession of in and out and progressive movements which is for the purpose of distributing the heat and preventing burning through the plate at any one point. Great care must be taken in manipulating the flame so that a small portion of the overlapping sheet is welded

at a time in view of the probability of liquid lead running off and dropping. This requires careful adjustment of the torch to give exactly the desired size of flame and careful manipulation by the operator to hold the surface metal near the fusing point and still avoid rendering the material too fluid.

The cross section of the lead filler or "burning bars" depends on the thickness or weight of lead to be welded; $\frac{1}{8}$ in. wire size is recommended for 2 and 3 lb. lead; $\frac{1}{4}$ in. for 3½-5 lb. lead; $\frac{3}{8}$ in. for 6-8 lb. lead; and $\frac{1}{2}$ in. and $\frac{3}{4}$ in., depending on the type of seams, for 10, 12, 16 and 20 lb. lead.

The importance of using lead welding rods of the correct size for each weight of lead can hardly be over-emphasized. If the bar is too light, the time required to fuse the lead needed for each deposit permits oxidation to take place due to the fact that the metal is light and is likely to be overheated. If a heavy bar is used with a small flame, the metal does not melt sufficiently to carry on the seam, and the seam chills during the lost time period while the flame is melting the lead. Fusing the filler is done over the sheet of course, and the time interval between fusing the burning bar and depositing it on the sheet must be carefully gaged.

K. Magnesium Alloys*—The chief methods employed are gas welding, electric resistance seam and spot welding, and electric resistance butt welding. The magnesium sheet alloys have good oxy-acetylene welding characteristics. Cast, extruded or forged fittings to be welded into magnesium sheet structures should be of the same alloy composition as the magnesium sheet.

The approximate compositions of the standard wrought magnesium alloys, suitable for welding, are as follows:

No.	Al	Mn	Zn	Mg
1	4.0	0.4	...	Balance
2	3.0	0.4	1.0	"
3	.	1.5	...	"
4	6.5	0.3	0.75	"
5	6.8	0.3	1.25	"

In the extruded form the first two alloys above are also readily oxy-acetylene welded. The third alloy is weldable only in relatively short seams. The gas welding of other extrusion alloys, while possible to a limited extent, is at present not recommended.

Gas Welding—The oxy-acetylene flame offers a protection to the molten metal due to the formation of a protective atmosphere. Welding magnesium alloys with the oxy-hydrogen flame requires considerably more skill and is therefore not recommended. The procedure, so far as the manipulation of the flame is concerned, is similar to that employed for aluminum and other metals. It has frequently been found that magnesium parts can be welded more rapidly than aluminum, due to their lower heat capacity. Holding the flame sideways at an angle of 30-45° to the work will produce the best results. When welding thin sheet, this angle should not exceed about 30° to keep the flame from burning holes in the sheet.

The welding rod should in general be of the approximate composition of the work to be welded. The size of welding rod should bear a relation to the thickness of sections for which they are to be used as follows: $\frac{1}{8}$ in. rod should be used for thicknesses up to 0.060 in.; $\frac{3}{16}$ in. rod for thicknesses from 0.050-0.110 in.; $\frac{1}{4}$ in. rod for thicknesses from 0.100-0.220 in., and $\frac{5}{16}$ in. rod for thicknesses of 0.200 in. and over.

After welding traces of welding flux should be carefully removed from the unused portion of the welding rod. Strips cut from sheet may be used instead of welding rod if no rod is available. Welded seams made with strip, however, are less uniform than seams made with rod.

A special welding flux supplied by the producers of the alloys is advisable for welding magnesium. The flux is applied to the welding rod and to the parts to be welded. As the welding flux must be completely removed after welding, only butt welding is permissible. Lap welds or any type of weld that may produce pockets or corners where flux might become entrapped must be avoided. Illustrations of this type are shown in Fig. 1. Instead, the joints should be designed as shown in Fig. 2.

The pieces to be welded must first be carefully fitted. Oil or grease should be removed from the areas to be welded with naphtha, gasoline, carbon tetrachloride or

*By H. Menking, American Magnesium Corp., Cleveland.

hot alkaline cleaners. The edges of sheet to be welded and the adjacent part of the sheet surface (about $\frac{1}{4}$ in. wide) should then be carefully cleaned and brightened by wire brushing, filing, or scraping. The joints to be welded require different preparation depending on sheet thickness, in accordance with Fig. 3. Sheet of thin

Fig. 1

Fig. 2

Fig. 3

Fig. 4

Fig. 5

gages (up to 0.040 in.) is flanged about $\frac{1}{8}$ in. as shown in Fig. 3, and the flange is welded down into a plain butt. For heavier gages, from 0.125 in. and greater, it is advisable to notch the edges with a cold chisel to facilitate penetration of the weld. The notches should be about $\frac{1}{8}$ in. deep and $\frac{1}{8}$ in. apart.

Castings or extrusions can be welded to sheet if their section is reduced by filing to the approximate thickness of the sheet to which they are to be joined. Sections of slightly different thickness may at times be welded to each other if the heavier section is preheated, so that both edges of the seam will begin to melt and flow at the same time. Rivets of aluminum alloys, when used in magnesium construction, must not be welded over as this results in a brittle alloy of uncertain composition.

Welding Procedure—After fitting and cleaning the pieces to be welded, they should be preheated with the torch to about 500-600°F. and the flux applied to the sheet edges and to the rod. The seams should next be tacked at intervals of from $\frac{1}{2}$ -1 $\frac{1}{2}$ in., depending on the type of work. A distance of 1-2 in. is then completely welded on each end of the weld in order to minimize warping in the subsequent welding of the seam. Any sheet which tends to warp during tacking should then be straightened out with a wooden hammer while it is hot. After reheating the sheet and covering the tacked spots with flux, the entire seam should be completed and the sheet again straightened with a wooden hammer.

In order to obtain a smooth weld, it is desirable to keep the welding wire in the molten pool of metal and not remove it any oftener than necessary. To accomplish this, sufficient flux should be applied to the work and to the welding wire before welding so as to avoid the necessity of frequently renewing the flux on the welding wire. If any portions of the weld should begin to oxidize, the work must be stopped and the oxidized portion carefully scraped or filed out. The cross section of a proper weld is shown in Fig. 4. Welds with cross sections as shown in Fig. 5 should be avoided.

Weld Cleaning—After welding, the flux must be carefully removed with hot water and a wire brush. The welded part should then be given the chromium pickle or dichromating treatment. This treatment is applied by dipping for about 1 min. in a solution made according to the following formula:

Sodium dichromate ($\text{Na}_2\text{Cr}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$).....	1.5 lb.
Concentrated nitric acid (sp.gr. = 1.42).....	1.5 pints
Water.....	to make 1 gal.

The welded article is then allowed to drain, rinsed in cold running water and placed for at least 2 hrs. in a container with hot water containing about 0.5% sodium dichromate. Finally the part should be carefully dried, preferably with a heated air blast. Lacquering of the completed seam is an excellent precaution and insures stability.

Fig. 6

Electric Resistance Welding—Spot, seam or butt welded joints are used to an increasing extent in magnesium structures. They combine high strength with economy in operation. The absence of any welding flux insures stability without any special precautions.

Magnesium sheet and extrusion alloys spot weld satisfactorily. The different alloys of sheet and extrusion alloys may be spot welded to each other, although the use of the same alloy is preferred. Magnesium sheet may also be spot welded to magnesium alloy castings of not more than about $\frac{1}{4}$ in. wall thickness.

Ordinary copper is unsatisfactory for electrodes as the high pressure employed distorts the contacting surface. This deformation can be avoided by using one of the special hard high conductivity, copper-base alloys made for this purpose. The tips of the electrode should be kept clean by frequent dressing to obtain uniform results and to avoid a rough surface of the spot and alloying of the tip material with the sheet.

Both the surfaces to be welded and those contacting the electrodes should be cleaned of oil and dirt and brightened with sandpaper, emery cloth, or by wire brushing before welding is started.

After welding, the spots should be wire brushed and dichromated. The two hour period of immersing in hot water, as applied on gas welds, may be dispensed with, as no welding flux is used in spot welding.

Electric seam welds may be used on all sheet alloys and most of the extrusion alloys. For seam welding, equipment with the same general characteristics as described for spot welds is required, the main difference being that the electrodes are power driven rollers. Electronic timing equipment is used to provide interrupted power impulses. Electric seam welds may be of the continuous or the intermittent type. The continuous seam weld which is really a succession of overlapping spot welds will produce gas tight joints. The intermittent seam weld produces joints similar to spot welds, but at lower cost since the operation is faster and fully automatic. Recommendations given under spot welding for cleaning of the electrodes and the magnesium parts to be welded also apply to seam welding.

Successful resistance butt welds may be made in extruded sections of the standard magnesium extrusion alloys (6.5% Al, 0.75% Zn, 0.3% Mn alloy and 4% Al-0.4% Mn alloy) and tensile strengths of about 26,000-43,000 psi. with 3-8% elongation, depending on the size and shape of the welded section, are obtained. Best results are obtained with a combination of flash and push welding in which, after the initial melting, the ends to be welded are rammed together by a predetermined amount controlled by a cam. Straight push welding in which the pressure is exerted by air or by hand is not recommended. The amount of current used is considerably lower than that used for aluminum. Many sizes of bars and various shapes ranging from 0.080-1 in. in thickness and from 0.150 in. to 1.0 sq. in. in cross section have been successfully welded by this method.

Welding of Castings—Minor defects in magnesium alloy castings such as sand holes may be repaired by oxy-acetylene welding provided that the casting is not to be highly stressed in service. To prevent cracking, the casting to be repaired should be heated to about 600°F. For more complicated castings, slow heating in an oven to avoid cracking is essential and the rate of heating should not exceed 100°F. per hour. Simple castings only may be heated with a gas flame. Immediately after welding, the casting should be put back in the oven to insure slow cooling. The rate of cooling should not exceed 100°F. per hour to avoid cracking.

The portions to be welded must be cleaned with a chisel or file and the outside oxide layer removed with a wire brush or scraper. The edges should be beveled or notched unless the wall is extremely thin (about $\frac{1}{8}$ in.). On walls of $\frac{1}{2}$ in. thickness or more, beveling both sides as shown in Fig. 3 is recommended. If a larger sized groove is to be welded, a suitable cast plate with beveled edges should be provided and fitted to the groove with $\frac{1}{8}$ in. play and welded in place.

The flux is brushed on the edges to be welded and on the welding rod. Because the density of the molten magnesium is close to that of the flux, care should be taken to prevent the freezing of any flux in the body of the weld. Blowing through the pool of molten metal with the flame after welding, will help to bring entrapped particles of flux to the surface.

After cooling down, the repaired portions should be thoroughly cleaned by scrubbing with hot water and a wire brush to remove all traces of flux. The built-up portion of the seam should then be ground down or machined off and again scrubbed with hot water and a wire brush. The casting should then be "dichromated," rinsed in cold water and kept in boiling water with 0.5% sodium dichromate

for 2 hr. Following this the casting should be placed in a steam chamber or above a container with boiling water for 24 hr., which treatment will bring out any traces of flux which may have escaped the cleaning. Castings showing flux spots on the weld after this period should not be returned to service but again put through the above washing, brushing and dipping treatment.

Welding castings requires more skill and care than welding magnesium sheet and extrusions as the sections are heavier, making the elimination of flux inclusions more difficult. However, by carefully following the above recommendations, good results can be obtained in repairing surface defects in lightly stressed castings. Highly stressed castings should not be welded. The strength of welded seams in castings of $\frac{1}{4}$ in. wall thickness is about 21,000 psi. with an elongation of 1-2%. Heat treating the welds is at present not recommended.

Stress Relieving—In the fabrication of welded members, varying degrees of stress may be set up within the metal adjacent to the welds, depending upon the size and thickness of the adjoining sections, the number of welds, their location, and the welding procedure. Members subjected to stress may be given a suitable heat treatment, usually in the form of a low temperature annealing (below the critical point).

This form of heat treatment, which is commonly referred to as "stress relieving", removes the greater part of the stresses set up by the welding operations. It involves heating the welded members to a temperature of from 1100-1200°F.

This "stress relief" treatment consists of heating the welded part uniformly to a temperature of at least 1100°F., holding it at that temperature for one hour for each inch of thickness of the thickest part welded, and then slowly cooling it in the furnace down to at least 200°F., after which it may be cooled in the air. It is not advisable to raise the temperature at a rate of over 125°F. per hour and the maximum temperature should not exceed 1200°F. The parts should be so loaded in the furnace as to be free from deformation.

In this connection it is of interest to note the requirements of the Am. Soc. Mech. Engrs. Unfired Pressure Vessel Code for stress relief of welded structures, which reads as follows:

All fusion welded vessels constructed in accordance with Par. U-68 (Class 1), shall be stress relieved. Vessels constructed in accordance with Par. U-69 (Class 2), shall be stress relieved where both the wall thickness is greater than 0.58 in., and the shell diameter less than 20 in., and for other wall thicknesses and shell diameters, where the ratio of the diameter to the cube of the shell thickness is less than 100.

Where stress relieving is required it shall be done by heating uniformly to at least 1100°F., and up to 1200°F. or higher, if this can be done without distortion. The structure or parts of the structure shall be brought slowly up to the specified temperature and held at that temperature for a period of time proportioned on the basis of at least one hour per inch of thickness and shall be allowed to cool slowly in a still atmosphere.

The structure shall be stress relieved by any of the following methods.

- (1) Heating the complete vessel as a unit.
- (2) Heating a complete section of the vessel (head or course) containing the part or parts to be stress relieved before attachment to other sections of the vessel.
- (3) In cases where the vessel is stress relieved in sections, stress relieving the final girth joints by heating uniformly a circumferential band having a minimum width of six times the plate thickness on each side of the welded seam in such a manner that the entire band shall be brought up to the temperature and held for the time specified above for stress relieving.
- (4) Nozzles or welded attachments for which stress relief is required, may be locally stress relieved by heating a circular area around the nozzle or attachment provided any part of the welded edge thereof is not less than $12t$ (t = thickness of plate) from the nearest adjacent welded joint or other element that would tend to restrict the free expansive movement of the heated area. The outside dimensions of this annular ring to be heated shall be at least $6t$ away from the outermost weld but not less than 5 in., and the entire area shall be heated simultaneously.

Bronze Welding—The term *bronze welding* is understood by the welding operator to refer to the joining of the high melting point metals, such as cast iron, nickel, and copper, by the use of bronze weld metal. Actually, the word "bronze" is not correct, as the alloys are in some cases brasses. For many welding applications, bronze welding offers advantages of speed, economy, and ability to do jobs which might otherwise be difficult or impossible.

Bronze welding is essentially an application of the oxy-acetylene process in which the joints produced are not true fusion welds, as the base metal is not melted, although a molecular union is evidently formed between the deposited metal and the base metal as explained below. Bronze forms a strong bond with metal surfaces which have been heated to the proper temperature and treated with a suitable flux. A properly made bronze weld is quite comparable in strength to a true

fusion weld. The heat required for the preparation of the edges to be joined and the melting of the welding rod is supplied by the oxy-acetylene flame. Because of the lower melting point of the rods used for bronze welding as compared with that of the material to be joined and the fact that the parts to be joined are required to be brought up only to a temperature where tinning and amalgamation with the bronze takes place, a much lower welding temperature is required in, for instance, the bronze welding of steel than in the making of a steel fusion weld.

Bronze welding with the electric arc may be accomplished by using a carbon arc and bronze or Monel metal filler rod, the arc being directed on the filler metal. Ferrous metals may be welded with bronze or Monel metal electrodes with the metallic arc process, although in this case, fusion of the base metal results. It should be noted, however, that the depth of fusion is not great.

Physical Nature of the Bronze Base Metal Bond—The character of the bronze base metal bond, which produces an adherence of bronze to base metal, in the case of cast iron, stronger than the base metal, has been investigated. It has been found that three distinct forces act to maintain adherence of the bronze to the base metal.

(1) **Tinning**—A clean metal surface will receive a thin film of a molten metal of low surface tension. The bond thus produced depends on the action of molecular forces at the bronze base metal interface.

(2) **Alloying**—A diffusion of the bronze constituents, copper, zinc, tin, and others into the base metal, and a corresponding diffusion of base metal constituents into the bronze takes place in a narrow zone at the bronze base metal interface. The base metal crystals, at the interface, when examined under the microscope, show that there is a diffusion of the bronze constituents into the crystal grains, and an alloying of the bronze metals with the base metal.

(3) **Intergranular Penetration**—The action of the molten bronze on the base metal surface opens up the crystal grain structure of the base metal surface and allows the bronze to penetrate the base metal along the grain boundaries. This alloying and intergranular penetration effect accounts for the great strength of the bronze base metal bond, which can be produced without surface fusion of the base metal.

Bronze Welding Rods—The bronze welding rod should tin readily when used with a suitable flux. It should be capable of building up a deposited metal that is practically free from defects due to slag inclusions, or blowholes. The fumes from zinc or other ingredients of the bronze should be kept at a minimum since they may interfere with the operator.

In general, the rods have a copper-zinc ratio of 60 to 40 and contain additions of tin, iron, manganese, or silicon, which improve the flowing qualities, deoxidize the weld metal, decrease the tendency to fume, and increase the hardness of the deposited metal for greater wear resistance.

For use with the arc process, a phosphor bronze or Monel electrode may be used. When heavily coated electrodes are used, the coating aids in promoting easy flow of metal.

Physical Properties of Bronze Welds—When the usual copper-zinc-tin rod is used for welding steel, a tensile strength of about 41,000 psi. on unreinforced coupons can be readily obtained. The fracture is usually through the weld metal and shows some porosity, although the general quality of the metal is good. When the manganese bronze rods are used, the strength may be somewhat greater, averaging about 46,000 psi., but the porosity in the metal is somewhat increased.

Typical Bronze Welding Test Data (Oxy-Acetylene)

Type of Coupon	Alloy	Psi.		% Elongation 2 in.	Bend Test	Brinell
		Yield Point	Ultimate Strength			
All weld metal	Copper-tin-zinc	13,500	46,500	25.0	68-72
As deposited	Manganese bronze	17,000	48,000	8.0	74-79
Bronze welded	Copper-tin-zinc	40,000	41,000*	10-12
Steel coupons	Manganese bronze	41,000	46,500*	10-12

*All average of 5 coupons. Reinforcement removed from all specimens.

Advantages—There are several advantages for bronze welding. Because of the lower temperature at which the bronze can be added to the base metal, there is an increase in speed of making the joint, and less heat is required than to make a

true fusion weld. Metallurgically the bronzes have a characteristic of yielding readily as they cool until the temperature is below 500°F., and there is an appreciable yielding under reasonably low stresses even at atmospheric temperature. This yielding as a single operation does not weaken the deposited bronze metal. Therefore, locked up stresses are reduced materially in a casting that has been welded with bronze.

Bronze welding should not be used where the finished work is to be subjected to temperatures above 500°F. It has also been learned that bronze should not be used where relatively high stresses such as 15,000 psi. may be applied to the finished work with such rapidity as to cause fatigue of the metal. Inasmuch as iron castings are seldom subject to stresses in excess of 5,000 psi., this effect can never be an important one in the bronze welding of cast iron. This same comment can be made with regard to bronze welding of malleable iron.

Inspection and Testing of Welds—Large installations of equipment fabricated by fusion welding are generally made under some form of purchaser inspection. In some welding applications, the inspection is called upon to conform to some code of construction requirements, and tests are specified to govern the qualification of the welding operator or the quality of the welding performed.

The tests that have been devised include destructive tests and nondestructive tests. Only the destructive tests are definitely quantitative, as the nondestructive tests are indicative of quality only, and some of these are indicative only to a limited extent. The destructive tests embrace the following: Tensile, bend, specific gravity, nick-break tests, impact, and hardness tests. The nondestructive tests that have been used on welded joints embrace the visual, the stethoscope, X-ray, and gamma ray tests; electric resistance and magnetic tests have been developed and are being used successfully in many instances. The hydrostatic proof test is a form of nondestructive test that is used for pressure vessels and closed containers.

Visual inspection of fusion welding while in process is also possible, although not generally specified directly. For this the fusion welded joint offers the peculiar advantage in that the inside of the joint may be observed while it is being made. Visual inspection requires a careful observer, properly trained, but it is valuable in studying procedure. The inspector watches the rod or electrode and observes how it melts down, notes the fusion and penetration and listens to the sound of the arc, or observes the flame adjustment of the torch. All of these items properly studied and understood will give a skilled inspector considerable information regarding the quality of the weld under observation.

Tensile Test—The tensile specimen of the joint is usually taken transversely with the weld in the center of the specimen, which conforms to the A.S.T.M. standard for flat plate tensile specimens, Fig. 7. The weld reinforcement may be removed or not, depending on the information sought.

Fig. 7—Tensile specimen for testing welds.

It is customary to obtain from the tension test the yield point and elongation. For high quality welds the yield point will be that of the base metal and the elongation will be of little value, particularly when the weld is stronger than the plate. The ductility of the weld metal in such cases is best obtained by means of the free bend test.

In order to obtain the tensile strength, yield point, elongation, and reduction of area of the weld metal, all weld metal specimens are taken longitudinally from the weld. The specimen can be taken only from welds in plate $\frac{5}{16}$ in. thick or

more. Smaller proportionate specimens can be taken from welds in thinner plate, a $\frac{1}{2}$ in. diameter specimen with 1.5 in. gage length may be used. The all weld metal tension test piece gives reliable data as to the physical properties of the weld metal, and is required by the Am. Soc. Mech. Engrs. Code and by the Am. Welding Soc. Specifications for filler metal.

For evaluation of fillet welds a tension test is commonly applied to a specimen formed by fillet welding two splice bars to opposite sides of two butted test bars, the fillet welds being made either longitudinally or transversely along the edges of the splice bars; in either case the resulting failure of the fillet weld is a shear failure and the stress is recorded in pounds per lineal inch, which for any average size of fillet, serves as a ready means of comparison.

In the case of thin wall welded tubing it is of course impossible to obtain the regulation tensile test specimens and a drift test (Fig. 8) has been devised to determine the strength of the weld. This simple test consists of forcing a tapered hardened steel drift into the end of the longitudinally welded tube. It may be driven by a hammer, or forced in with a press, which method is more desirable since it eliminates the factor of shock. The tube end is gradually expanded until failure occurs by splitting, usually outside the welded area, showing the weld to be stronger

Fig. 8—Drift and compression tests for welded tubing.

Fig. 9—Bend test for testing welds.

than the base metal and to have adequate toughness and ductility. The distance the drift is forced into the tube may be taken as a measure of the ductility of the welded tube. Since this test stretches the welded joint, its action is quite similar to that of the tensile test.

If a short length of welded tubing is placed axially in a compression machine and loaded, it will collapse like a bellows, and in so doing will be subjected to shear, tensile, and bending stresses. This qualitative test for ductility

affords a good evaluation of the flanging qualities of the welded tube. Of course, a simple flanging operation will be an adequate test of the ability of the welded tube to withstand flanging operations, but this test is not so severe as the crush test. The hydrostatic test to destruction which is applied in some instances to pressure vessels and closed containers to determine their ultimate strength, as well as also the character of their failure, is an extension of the tensile test. It is a form of test, however, that can be applied only in connection with design studies and research and it is not necessarily a test of the welded joint, as the vessel may rupture at a place apart from the weld. This test is intrinsically a test of the entire

structure and will reveal the weakest part or place, whether it be the weld or the solid metal.

Bend Test—Since the tensile test in flat specimens gives no quantitative measurement as to the ductility of the welded joint, the free bend test was devised to furnish this much needed information. The free bend tests yield quantitative data independent of the thickness of the specimen provided the width is at least three times the thickness. However, the Am. Soc. Mech. Engrs. Code calls for a width one and one-half times the thickness.

Fig. 9 shows the design of the bend specimen and the method of preparation. After the initial bends are made, the specimen is placed as a strut in a vise or press and bent until failure occurs on the outside bent surface between the gage marks. Corner cracks are not considered failures. Any failure on the surface is not considered as such until its greater dimension is $\frac{1}{8}$ in. or more. The elongation of the outside fibers is measured directly with a flexible scale or it can be calculated from the curvature by the formula $\frac{100 \cdot t}{2R}$ where t is the thickness and R the radius to the

neutral plane. The ductility can also be measured by means of a bend extensometer. However, direct measurement is the more satisfactory. For specimens $\frac{1}{4}$ in. or more in thickness, a heavy press or tensile testing machine is desirable.

Root break and side bend tests are new forms of the bend test that have been introduced to reveal lack of soundness in welded joints, but they have not as yet met with general acceptance. The root break test is applied by bending the specimen backward, so as to stretch the bottom of the vee of a single vee weld; it is particularly effective in revealing lack of penetration and soundness at the bottom of the vee. The side bend test is applied by bending a thin specimen taken transversely across the welded joint so that the length of the weld is perpendicular to the plane of the specimen; this test, which is said to be particularly effective

Fig. 10—Nick-break test.

Fig. 11—Test specimen for fillet welds.

in revealing lack of side wall fusion in the vee or groove, is a new one that has been introduced and recommended by the United States Navy Dept., as superior to the widely used nick-break test.

Specific Gravity Test—This test is made to insure freedom from fine porosity and is carried out on a solid cylinder of the weld metal $\frac{1}{8}$ in. dia. x 2 in. long. The weight of the specimen and its volume in metric units are carefully determined, and the weight in grams divided by the volume in cubic centimeters gives the specific gravity. For highest class weld metal a specific gravity of 7.80 is required.

Nick-Break Test—This test consists of rupturing, with a sudden blow, a specimen notched in the weld. It is a homogeneity test and indicates the soundness of the weld by showing on the fractured surface (1) whether complete penetration has been obtained; (2) the presence of oxide or slag inclusions; and (3) the degree of porosity, which should not exceed six gas pockets or holes per square inch of fractured surface. The maximum dimensions of any defect should not exceed $\frac{1}{8}$ in.

The materials required to make the test are a vise or anvil in or against which the specimen is clamped; a heavy hammer for applying the blow, and a specimen whose width is $1\frac{1}{2}t$ plus $\frac{1}{4}$ in., slotted at the edges with a hacksaw for a depth not greater than $\frac{1}{4}$ in. No machining is required on the specimen. With material $\frac{1}{4}$ in. or greater in thickness, the specimen may be laid on supports about 6 in. apart and fractured by a power hammer, or falling weight of sufficient intensity to cause

sudden fracture. Examination of the fractured surface will reveal the presence of porosity, oxide, or lack of fusion.

Although the test is extremely simple, it is severe and only good quality weld metal and welding will pass the test. It constitutes one of the requirements for the qualification of welders in the Am. Soc. Mech. Engrs. Unfired Pressure Vessel Code for Class II Vessels. The specimen is shown in Fig. 10.

For fillet welds, a test equivalent to the nick-break test is applied to a so-called fillet weld break specimen (Fig. 11). This specimen is formed by fillet welding one flat plate or bar at right angle to another, in such a manner that by application of pressure or a blow to one edge of the specimen the fillet weld may be opened up at its root. The resulting fracture in the weld reveals any lack of penetration or soundness.

Impact Tests—The Izod and the Charpy impact tests are generally used. These tests are carried out by fracturing a notched specimen with a swinging pendulum and measuring the energy absorbed in breaking the test piece. The tests are described elsewhere in this Handbook.

It is customary in testing the impact strength of welds to take at least three specimens, placing the notch at the bottom of the weld in one; at the side in another, and at the top in the third, and taking the average of the three results as the impact value in ft-lb.

Hardness Tests—The hardness test is used considerably in the laboratory but has not been used to any great extent in the field for weld testing, except for determining the hardness of built up rail ends. The machines more generally used for hardness testing of welds are the Brinell, Rockwell, and scleroscope. A description of these instruments and the hardness test are given elsewhere in this Handbook.

Stethoscope—The object of the stethoscopic test is to determine by means of the sound a weld gives off when tapped with a hammer, whether the metal is sound or contains defects, such as lack of fusion or cracks. Just as a sound bell gives off a clear ringing note and a cracked bell a reedy note, so good weld metal gives a good ringing sound and a poor weld a flat sound or note.

In order to readily identify the sound an ordinary physician's stethoscope is used, the extra precaution being taken of protecting the end with rubber to avoid any extraneous sounds resulting from scraping the stethoscope on the metal.

Fig. 12—Stethoscope testing of welds.

The stethoscopic test has been applied successfully to pressure vessels, locomotive staybolts, and welded structures. See Fig. 12.

X-Ray—Metals can be X-rayed and their internal defects made visible on photographic films. In this way all types of defects such as cracks, slag, blowholes, and lack of fusion can be detected. Generally the method consists of placing the X-ray tube on one side and the film on the other of the piece being tested. After an exposure ranging from a

fraction of a minute to fifteen minutes, depending on the power of the tube and the thickness of the metal, the film is developed and examined for defects in the weld.

This method has found wide industrial use and is recognized as the foremost nondestructive test. It is one of the requirements of the Am. Soc. Mech. Engrs. Code for Class I welded pressure vessels.

Gamma Ray Tests—Gamma ray tests are similar in method to X-ray tests. The gamma ray emanating from radium penetrates metals rapidly and is more applicable to heavy sections which would require unusually long exposure by X-rays. It has been successfully applied to heavy castings such as are used in ship construction. On heavy work overnight exposures are employed.

In application several large castings may be arranged radially around a capsula, containing radium at the center. The films for recording the results are placed on

the opposite side of the casting from the radium. Before attempting the use of radium for gamma ray testing, it is essential that the operator be familiar with the properties of radium, and that the necessary precautions be taken to protect those handling it.

Codes and Specifications—Specifications covering construction projects in many fields, are including fusion welding as an acceptable means of fabrication in a majority of cases. On important projects, furthermore, a good many specifications include the manner in which the welding must be carried out and the result which must be obtained. The following extracts and resumes of codes and specifications are given therefore, for the purpose of indicating in general the manner in which various applications of fusion welding are being covered:

A.S.M.E. Boiler Construction Code—The welding rules in the various sections of this Code were initially adopted by the Am. Soc. Mech. Engrs. Boiler Code Committee in 1931. Those in the power boiler section were so drawn as to apply solely to shells and drums and there are no provisions in that section as yet for welding applied to carry stress in furnace construction, water legs, stays, or braces. Those in the heating boiler section permit welding in all parts of the boiler structure without restriction. The welding rules in the unfired pressure vessel section are so drawn as to provide for three definite classes of vessels according to the treatment of the welds and the tests applied. The welding rules in the miniature boiler sections are similar to the so-called Class 2 rules of the Unfired Pressure Vessel Code.

There have recently been added in the unfired pressure vessel section a comprehensive set of rules for vessels subject to external pressure and jacketed vessels which provide for both welded construction and welded attachment of reinforcing rings and flanges. Both the power boiler and the unfired pressure vessel sections have recently been amplified to provide for welded attachment of nozzles, domes, flanges, and flat heads.

Copies of the several sections of this Code may be obtained from the office of the Secretary of the Am. Soc. of Mech. Engrs., 29 West 39th St., New York.

A.P.I.-A.S.M.E. Unfired Pressure Vessel Code—As a result of the exemption in the Am. Soc. Mech. Engrs. Unfired Pressure Vessel Code of vessels for use with petroleum liquids and gases, a joint committee of the two above organizations has recently prepared a specialized pressure vessel code to meet the needs of the petroleum industry. This new Code is worthy of mention as it has been so drawn as to provide adequately for the improved processes and methods of petroleum refining which involve extremely high pressures and temperatures, with attendant rapid corrosion rates. These rules are drawn up at considerable variance with the corresponding rules in the Am. Soc. Mech. Engrs. Unfired Pressure Vessel Code, both as to detail requirements and the scope of construction and repair work covered. Considerably lower factors of safety are here provided for, due to the stringent inspection requirements which form an integral part thereof.

Copies of this Code are available at the office of the Secretary of the Am. Soc. of Mech. Engrs., 29 West 39th St., New York.

U. S. Department of Navigation and Steamboat Inspection—The Marine Boiler Construction Rules of this Federal Department, which has been in existence for nearly sixty years, have recently been revised so as to provide for welded construction and repair of both boilers and pressure vessels. The new Code is divided into two sections, one embracing specifications for the materials and the working stresses allowed, and the other pertaining to the design, construction, installation, inspection, and repair of boiler, pressure vessels, and piping systems; the construction rules of the latter part bear a close similarity to the corresponding rules in the Am. Soc. Mech. Engrs. Boiler Code.

The welding rules in this new Code cover the shells and drums of power boilers, three classes of pressure vessels, and the various types of piping and pipe fittings. The welding rules for this Code are somewhat more stringent and restrictive than the corresponding requirements in the Am. Soc. Mech. Engrs. Boiler Code on account of the particularly hazardous conditions encountered on shipboard. They include the new rules for welded attachment of nozzles, domes, flanges, and flat heads which are incorporated in the Am. Soc. Mech. Engrs. Boiler Code.

Copies of this new Code are obtainable from the office of the Bureau of Navigation and Steamboat Inspection, Department of Commerce, Washington, D. C.

U. S. Navy Department—Specifications for Arc Welding and Specifications for Welded Boiler Drums can be obtained upon application to the Bureau of Engineering, U. S. Navy Department, Washington, D. C.

National Board Rules for Repair of Boilers by Fusion Welding—These rules have been formulated by the National Bureau of Casualty and Surety Underwriters in co-operation with the National Board of Boiler and Pressure Vessel Inspectors, to indicate the extent to which fusion welding is acceptable to the authorities for steam boiler repairs. These rules have been reviewed by the Am. Soc. Mech. Engrs. Boiler Code Committee and pronounced consistent with the power boiler rules in the Am. Soc. Mech. Engrs. Boiler Code. They embrace such applications as welding in staybolted surfaces, welding cracks in circumferential seams of boiler shells, welding cracks in tube ligaments, closure of openings in shells or drums by welded patch plates, safe ending of boiler tubes and welding of cracks and fractures in cast iron heating boilers.

Copies of these rules may be obtained upon application to the National Bureau of Casualty and Surety Underwriters, No. 1 Park Ave., New York.

A.S.A. Pressure Piping Code—The recent issuance of this Code under the sponsorship of the Am. Soc. of Mech. Engrs. has filled a long-felt want in the field of pressure piping. This Code embraces construction requirements for all classes of piping, which include steam and power piping, gas and air piping, oil piping, and piping for district heating purposes. One section is

devoted to fabricating details under which there is a subdivision covering welding and welded fabrication.

Copies of the new Code may be obtained upon application from the office of the Secretary of the Am. Soc. of Mech. Engrs., 29 West 39th St., New York.

Manual of Heating and Piping Contractors' National Association—This is a Handbook covering welded pipe fabrication that has been prepared by this Association for the benefit of architects, consulting engineers, and the piping contractors who are in need of fundamental data on the subject. It contains instructional material for the use of fabricating contractors in training pipe fitters and apprentices to perform welding and is not written in the form of a Code. It contains much important fabricating data and will serve as a valuable guide in both design and construction work.

This Manual can be obtained from the office of the Heating, Piping and Air Conditioning Contractors' National Association, 1250 Sixth Ave., New York.

Rules for Fusion Welding of Gravity Tanks, Tank Risers, and Towers—This is a set of rules that was prepared by a joint committee of the International Acetylene Association and the Am. Welding Soc. to provide for the fusion welding of the above essential parts of sprinkler fire protection systems. This work was undertaken at the specific request of the National Board of Fire Underwriters, which is frequently confronted with the question of welded construction.

Copies of these rules may be obtained upon application to the office of the Secretary of the International Acetylene Association, 30 East 42nd St., New York.

Rules for Welded Construction of Oil Storage Tanks—This is a proposed Code that is receiving the joint consideration of the Am. Welding Soc. and the American Petroleum Institute. It applies to the large above-ground bulk storage tanks that are used by the petroleum companies. The American Petroleum Institute has issued a tentative draft of a proposed Code, but the code under consideration by the Am. Welding Soc. has not as yet been issued.

For information concerning the tentative draft of the American Petroleum Institute application should be made to the office of the Secretary, 50 West 50th St., New York.

Rules for the Fusion Welding of Marine Buoys—This is a Code that has been drafted by the joint activity of the International Acetylene Association and the Am. Welding Soc. for the benefit of the U. S. Bureau of Lighthouses. The scope of the work is to cover not only the plain buoys which require welded shell fabrication but also the light, bell, and whistle buoys which require elements of structural steel work in addition. This Code has not as yet been issued.

A.W.S. Building Code—The latest edition of this Code was issued in 1934 by the Am. Welding Soc. for the guidance of erectors in applying fusion welding and gas cutting.

Information concerning the Code can be obtained upon application to the office of the Secretary of the Am. Welding Soc., 33 West 39th St., New York.

Specification for the Design, Construction, Alteration, and Repair of Railway and Highway Bridges—This Code issued by the Am. Welding Soc., 33 West 39th St., New York, has for its purpose to codify all applications of fusion welding to the construction, maintenance, and repair of steel bridges for both railway and highway usage.

Tentative Code for Fusion Welding and Flame Cutting in Machinery Construction—This Code was issued in 1935 by the Am. Welding Soc. The purpose is to draft rules for machinery construction that will be comparable to those now effective for fusion welding and gas cutting in building construction.

Qualification Tests for Welding Operators—These rules are general in character, having been prepared by the International Acetylene Association to cover the average conditions encountered in welding shop applications and provide for the testing of operators with the least possible time and expense. The tests cover a wide range of materials and types of fabrication.

These rules have been issued in pamphlet form and can be obtained upon application to the office of the Secretary of the International Acetylene Association, 30 East 42nd St., New York.

Specifications for Filler Metal—The Am. Welding Soc. has, after a number of years of study and investigation, adopted as a tentative standard a set of Specifications for Filler Metal to be used in making fusion welded joints. These rules depart from the original thought of requirements pertaining to chemical composition and depend solely on the physical properties that are obtainable therefrom when deposited in the welded joint.

These Specifications were published in the Aug., 1933, issue of the Am. Welding Soc. Journal and can be obtained in pamphlet form upon application to the Secretary of the Am. Welding Soc., 33 West 39th St., New York.

A.S.T.M. Specifications for Steel Suitable for Fusion Welding—In recognition of the remarkable recent advance in the art of fusion welding, the A.S.T.M. has recently issued Specifications A 151-33 to list the classes of steel that are suitable for fusion welding. These Specifications refer to twenty established A.S.T.M. Specifications for rolled plate material, pipe and tubing, and wire which are known to be weldable with satisfactory results under ordinary commercial practices, provided the carbon content does not exceed 0.35%.

Copies of this Specification can be obtained from the office of the Secretary of the A.S.T.M., 260 South Broad St., Philadelphia.

Safe Practices in Fusion Welding—The question of Safe Practices in Fusion Welding is an important one, as there are inherent hazards in certain applications, no matter what the process of welding may be. Special attention will be devoted to the application hazards, as it is not the purpose here to enumerate the safety precautions that must be observed in connection with handling the different welding processes. The latter have been ably and comprehensively covered in the safety pamphlet on Gas and Electric Welding, issued by the National Safety Council as Safe Practices Pamphlet No. 23. This pamphlet embraces much valuable informa-

tion concerning the fundamentals of gas welding and cutting, thermit welding, and electric welding, and it should be consulted by everyone who has charge of fusion welding operations.

In all cases, operators of welding equipment have the advantage of the safe operating instructions that are furnished with all fusion welding equipment and should be conversant therewith. As a rule, welding equipment is so constituted that it is quite convenient to observe the usual precautions for safety, but in the application of the process involved, there are certain conditions and operations that may endanger the operator if the possibility is not anticipated and avoided. Some of these hazards will be enumerated.

Eye Protection—An important hazard in welding applications is that of injury to the eyes, from the heat and glare of the flame or arc, and from particles of hot metal that may fly up from the work. Properly colored lenses fitted in goggles will protect the eyes from the gas flame, but in the case of electric arc welding the intensity of the ultra-violet and infra-red rays is such that it is necessary for all persons exposed to use shields or helmets that will protect not only the eyes but the skin also. In the case of goggles, the lens should be selected with considerable care in order to obtain the desired visibility together with adequate eye protection; the exterior surfaces of these lenses may be to advantage protected from flying sparks by superimposing a clear glass lens over each. In the case of lens for use with the electric arc, the selection must be based on laboratory tests, as their transmission of ultra-violet and infra-red radiation cannot be determined by visual inspection; proper eye protection requires more than mere reduction of the glare. Goggle frames should be of noncombustible material and preferably a nonconductor of heat; if of metal they should be padded. The frames should have vent holes in the cups to provide ventilation back of the lenses.

Special precautions must be taken to protect other workers or passers-by from the harmful rays given off from arc welding operations. It is preferable to locate these jobs in special rooms. If this is impracticable, the operations should be screened or enclosed not only to prevent workers or passers-by from looking directly at the arc, but also to protect them from reflected rays as much as possible. Further protection against reflected rays is frequently provided by applying paint to the screen or enclosure and to other nearby surfaces. Zinc oxide combined with lamp black to produce a bluish gray color is satisfactory.

Clothing—The welding operator should have some protection from the heat of welding, particularly when working on heavy work and for long periods of time. In such case fire-resisting gauntlet gloves and aprons will serve as a protection against the radiated heat. Woollen clothing is to be preferred to cotton, as it is not so readily ignited and it protects the operator from changes in temperature. It is recommended that operators on arc welding wear only fireproofed outer clothing.

There have been instances when the operator's clothing has been set on fire by sparks of molten metal which lodge in rolled-up sleeves, and in pockets of clothing. Operators should be warned to keep sleeves buttoned around the wrist and their collars buttoned to prevent lodgment of sparks. Some suggest that it is advisable to eliminate pockets in front of overalls and aprons. A sheet iron screen in front of the worker's legs will provide further protection against sparks and molten metal in gas cutting.

Electric Installation—When installing and operating electric equipment, the provisions of the National Electrical Safety Code should be followed. The voltage is in most cases so low that there is little danger from shock from the welding circuit, but still the usual precautions should be taken. There are, however, some types of equipment that have a high voltage under open circuit conditions and these should be properly guarded.

Fire Protection—Where welding or cutting has to be done in the vicinity of combustible material, special precautions should be taken to make certain that sparks or hot slag from the welding or cutting operations do not reach combustible material and thus start a fire.

Cutting or welding work which can be transported should be removed to a safe location in a sprinklered or noncombustible building. If the work cannot be moved, exposed combustible material should if possible be moved a safe distance away, say 30 or 40 ft. Wherever there are floor openings or cracks in the flooring, it is also advisable to make certain that there are no highly combustible materials

on the floor below, where they would be exposed to sparks which might drop through the floor.

The sparks and hot slag should be watched to see that they do not come in contact with combustible material, do not lodge in floor cracks, and do not drop through holes to the floor below. Sheet metal guards or asbestos curtains should be used where needed; make sure that the guards and curtains are adequate. Because hot slag may roll along the floor for considerable distance, it is important when using asbestos blankets as a curtain that no openings exist where the curtain meets the floor. Avoid the use of tarpaulins as experience has shown that they do not provide adequate protection.

Extra men should be stationed with small hose, chemical extinguishers, or fire pails nearby when the nature of the work requires that blowpipes be used near wooden construction or in locations where the combustible material cannot be removed. In sprinklered buildings, maintain sprinkler protection without interruption while cutting blowpipes are being used. A man should be kept at the scene of the work for a half hour after completion to make sure that sparks have not started smoldering fires.

Dusty and gassy atmospheres in certain mines, mills, industrial plants, and plants spraying lacquers and the like require extra precautions to avoid explosions or fires from electric sparks, matches, and open fires. Welding or cutting in such suspicious places should therefore be done only when proper precautions have been taken and only after the responsible official in charge has inspected the situation and has personally given instructions to proceed.

Ventilation—When working in a confined space, be sure of proper and adequate ventilation, by natural means or by an air fan or blower. Oxygen should never be fed from a cylinder into a confined space as it is unsafe to do so. Welding or cutting in confined spaces is a job requiring special precautions. The operator should wear special clothing—preferably fireproofed, but certainly of wool.

When the operator is working in a confined space, always have a helper present outside of the confined space to close the cylinder valves or help in other cases of emergency. All equipment should be tested for leaks before taking it into such places, and when work is interrupted for any reason it should be brought out.

Welding on brass, bronze, or galvanized iron should be conducted in well ventilated locations and operators should be supplied with suitable respirators to prevent the inhalation of zinc fumes, particularly if the welding job is of any considerable duration. In the event of the workman experiencing any nausea after he has been welding brass, bronze, or galvanized iron, he should drink milk copiously. Where flame cutting has to be done on metal that has been surface coated with lead paint, the operator should be provided with a gas mask which will supply him fresh air uncontaminated with lead fumes.

Special Precautions—No welding or cutting should be done on used drums, barrels, tanks, or other containers until they have been cleaned so thoroughly as to make absolutely certain that no flammable materials are present. Where steam is available, this may be used to remove materials which are easily volatile. Washing with strong caustic soda solution will remove heavier oils. Even after thorough cleansing, the container should wherever possible be filled with water before any welding, cutting, or other hot work operation is performed. In practically every case it will be found possible to place the container in such a position that it can be kept filled with water to within a few inches of the point where welding or cutting is to be done. In doing this, care should be taken to make sure that there is a vent or opening to provide for the release of heated air from inside the container. This can usually be done by opening the bung, hand hole, or other fitting which is above the water level.

Where alterations or repairs are being carried out on large containers that have held flammable substances, periodic examination of the air contents of the vessels should be made from time to time wherever possible, by means of a gas detector where such an instrument is available. Although the vessel may have been steamed and flushed with soda there may still be traces of oil or grease under seams and the heat of the welding or cutting operations may cause such oil or grease to give off flammable vapor to the extent that an explosive mixture may be formed inside of the tank. If possible, keep a supply of carbon dioxide in the vessels while under the process of repair. The use of carbon tetrachloride for this

purpose is not recommended as carbon tetrachloride gives off a poisonous vapor when heated.

A jacketed vessel, tank or container should never be welded until after every possible precaution has been taken to vent the confined air sufficiently. A metal part which is suspiciously light is hollow inside, and should be drilled before heating. Otherwise it will act like a bomb.

Gas cutting should be used with judgment and care as to the effect upon the structure. No important structural member should be cut while it is under load, except where the removal of the part will not reduce the strength of the part. Also great caution should be used in cutting holes in or removing portions from structural members unless the design provides therefor without weakening. If gas cutting is used to remove rivets, great care should be used in removing the head, to avoid reducing the thickness of the base metal at the rivet hole. In cutting away any important or heavy member of a machine or structure, caution should be exercised to make sure that the severed part will not fall and cause damage to adjacent equipment. If the part is likely to fall and injure the operator or other workmen, care should be taken to properly support it while it is being cut. One of the common errors in cutting is to allow a part to fall on the operator's feet.

Health Protection—If painted or lead coated materials are cut or welded, the lead volatilizes and may be breathed into the operator's lungs, causing lead poisoning. In a similar way "zinc chills" may result from breathing the fumes when welding zinc, brass, bronze, or galvanized metal.

Under such conditions, ventilation must be depended on to protect the operators; or better yet, the operators should be required to wear special gas masks or fresh air masks.

Special care must be exercised when welding or cutting operations are carried on in confined and poorly ventilated spaces, such as in tanks, compartments, and holds of vessels. Artificial ventilation may be necessary to replace the oxygen consumed from the air and the operators should be under close observation by an outside attendant so help can be rendered immediately in an emergency.

Industrial Heating Furnaces

By M. H. Mawhinney*

Introduction—This article covers the electric and fuel fired furnaces for heat treating purposes, operating at all temperatures up to about 2400°F. It does not include melting furnaces, or electric furnaces of the arc type or the induction type.

Principles of Combustion—The combustion of fuel (solid, liquid, or gaseous) consists of the rapid oxidation of the combustible portion of the fuel to produce heat. The theoretical heat energy available depends upon the net calorific value of the combustible content, and the temperature produced depends upon the nature of the gaseous products to be heated by this available heat energy. When the combustible elements (usually C and H₂) are combined with the theoretically correct amount of air, the resulting products of combustion are confined to CO₂ and N₂ from the air, and water vapor. Excess O₂ in the flue gases serves as a measure of the air-fuel mixture on the lean side (too much air) and CO in the flue gases indicates the richness (too much fuel) of the fuel mixture.

Fuels are generally sold on the basis of the higher heating value in B.t.u., which is the gross chemical energy, while the net useful energy is the lower heating value, after the heat necessary to convert the water in the flue gases to vapor has been subtracted.

For most fuels (exclusive of producer gas and blast furnace gas) the amount of air required for combustion is about 1 cu.ft. for each 100 B.t.u. of lower heating value. Table I shows the physical characteristics of the principal fuels used in heating furnaces.

Fuels for Heat Treating—Where metallurgical requirements are rigid the most suitable combustible fuels are natural gas, liquefied petroleum gas, artificial gas, and oil. Of these fuels, the gases are the most satisfactory for temperature control and the maintenance of the proper atmosphere in the furnace, but equally good results are obtained with oil by care in furnace design and careful supervision of operation.

For rougher forms of heating (forging, forming, and rolling) the remaining fuels may be utilized, although the specifications on this class of heating are becoming more exacting, and considerable care and supervision is required to meet the requirements with fuels which do not lend themselves to consistently automatic control.

Methods of Heat Application—Methods of firing furnaces heated with combustible fuels include:

1. Recirculation system is used for low temperatures (usually under 1100°F.) where gas or oil is burned in a separate chamber and the resulting products of combustion are circulated through the furnace by a fan.
2. Indirect firing is used for all temperatures up to 1900°F., where combustion chambers are located below (underfired), at the side of (side fired), or above (overfired) the heating charge, and separated from the heating chamber by suitable baffles. (While indirect firing is more common at temperatures below 1900°F. it is possible to design a gas fired furnace so that it will operate satisfactorily from 1000–1900°F. and still have the firing direct into the furnace oven.)
3. Direct fired is used for temperatures above 1900°F. where the burners fire directly into the heating chamber, usually above the charge.

Burner Systems for Heating Furnaces—The various types of burners commonly used on heating furnaces are given in Table II.

The use of stacks in connection with heating furnaces is being gradually discontinued, because modern burners do not require stack draft, and because the usual failure to control the draft by proper damper operation results in large quantities of excess air in the furnace at low fuel rates.

Types of Electric Furnaces—Electric furnaces (resistor type is here considered) are ordinarily limited to those applications for which temperatures do not exceed 1900°F., because the life of the metal resistor elements is uneconomical above that temperature. Exceptions are the furnaces employing carbon resistor elements in granulated and bar forms at temperatures up to 2300°F., and furnaces containing protective atmospheres which have been successfully operated with metallic heating elements at 2100°F. for brazing.

The metallic heating elements commonly used are of heat resisting alloy in either rolled or cast form. In the rolled form the alloy wire or flat strip is looped on refractory or metal hangers to form a radiating grid on the sidewalls, roof, or bottom of the furnace. The cast alloy is cast in grids made up of similar loops of various cross sections, and the grid hung or supported on hangers and guides provided in the refractory lining of the furnace.

The disposition of the heating elements in the furnace is one of the principal considerations in the uniform transfer of heat to the heating charge. At the usual heat treating temperatures, from 85-95% of the heat in a furnace (electric or fuel fired) is transferred by radiation (the remainder by convection) and the radiating elements must be placed with consideration of the heat requirements. It is for this reason that more element area is provided adjacent to doors and other openings, where the heat requirement is relatively great.

Table II
Burners for Heat Treating Furnaces

Fuel	Designation	Approximate Pressure/Sq. in. Air		Comments
		Fuel	Air	
Oil and tar	Steam atomizing	10-40 lb.	¼-4 oz.	Steam at 60 lb. min. 40-50% induced air
	Low pressure	10-40 lb.	8-16 oz.	
Producer gas	Mixing type	2 in. water	4 oz.-5 lb.	Scrapers or steam jets for cleaning tar and soot
Blast furnace gas	Proportioning	3 oz.	8-16 oz.	Automatic air-gas mixing
Natural and artificial clean gases	Blast type, or nozzle mixing	4-8 oz.	3-16 oz.	{ Separate air and gas control, automatic mixing, all air inspired. Highly luminous flame
	Proportioning	3 oz.	8-16 oz.	
	High Pressure	10-25 lb.	Atmosphere	
	Luminous or radiant	3-8 oz.	3-8 oz.	

Characteristics of Electric Heat—Electric heat offers the following principal advantages over furnaces heated by the combustion of fuel:

1. Quietness and cleanliness of operation.
2. Consistency of operation and freedom from personal element resulting from adjustment of fuel. After initial adjustment, the electric furnace requires no further regulation of heat input.
3. Uniformity of temperature in those applications for which electric heat is applicable (certain applications, such as large masses and rough heating at high rates, are difficult with radiant electric heat).
4. Use of protective atmospheres without the necessity for muffles.

The principal disadvantages, in comparison with fuel fired furnaces are: (1) High B.t.u. cost of electricity; (2) less flexibility of adjustment where heat requirements fluctuate rapidly; and (3) slow heating up from a cold condition.

Design Data—It has been mentioned that the location of the elements is important in obtaining uniform furnace temperatures. Of equal importance is the current density carried on the elements. If the element area is too small, with consequent high release of energy in watts per square inch of element, the element temperature will exceed the furnace temperature to such an extent that local overheating of the charge adjacent to elements must result. This is particularly true at low temperatures of about 1000°F., where for best uniformity the energy liberation must be kept down to from 6-8 watts per sq. in. As the temperature is increased, higher rates are permissible, so that at 1500°F. the rate may be 10-12 watts per sq. in. Beyond 1500°F. the rate must again decrease on account of element failure, and at 2000°F., the rate of liberation should not exceed 8 watts per sq. in.

Where possible, electric furnaces are connected across the line which saves the expense of transformers, but frequently the elements based on line voltage are too light for satisfactory life and transformers are necessary.

Muffles—Where a perfectly consistent atmosphere must be maintained (as for bright annealing of metals), the leakage through joints prevents the use of refractory muffles, so metal muffles of heat resisting alloy (cast or rolled forms) must be used. The construction and maintenance of such muffles in any size is a mechanical problem involving a great many difficulties from warpage, due to uneven expansion and contraction.

The use of muffles decreases the heating capacity of a furnace about 20%, as compared to an open furnace, and the fuel consumption is increased by the necessity for higher temperatures outside the muffle and consequently greater radiation losses.

Pot Furnaces—Pot furnaces are frequently used in heat treating, and although costly and troublesome because of the necessity for pot replacement and losses of liquid heating medium, they have the advantages of no oxidation of heated materials, rapid and uniform heating, and ability to treat only a portion of a piece without affecting the remainder. Heat treating salts and lead are commonly used as the heating media.

The capacity of a salt pot for operation at 1500°F. in lb. of steel heated per hour is about 3/10 times the weight of salt in the pot. The usual consumption of lead is about ½ lb. per 100 lb. of steel treated and about 1 lb. of charcoal is used per hour for covering each square foot of lead bath. The average consumption of salts is about ½ lb. per 100 lb. steel at 1200°F. average bath temperature and about 7/10 lb. at 1500°F.

Material Handling in Furnaces—The selection of the best method of handling material through furnaces involves difficult problems. The following rules should always be followed:

1. A furnace is a heat treating machine and the method of conveying the material must not compromise the heating characteristics of the furnace.
2. The advantages of simplicity in design of hot conveyors should not be overlooked in a desire to save labor.
3. In the selection of conveying means, those which will damage the material under consideration must first be eliminated. Examples are the scratching of nonferrous metals, damage to threaded parts, sagging and denting of tubular products. Conveying means which interfere with the circulation of heat where precision of heat treatment is necessary, must also be eliminated.

The various methods of handling for industrial heating include:

Batch—The batch methods consist of the stationary hearth, solid bottom; stationary hearth, roller bottom; car bottom; and removable furnace covers and pits.

Semicontinuous—The semicontinuous method consists of a stationary hearth or car bottom furnaces in conjunction with handling forks or special cranes to reduce the time between charges to several minutes.

Continuous—The continuous methods consist of the pusher, direct or on pans or shoes; tunnel kilns, with cars; chain conveyor and moving fingers; walking beam; roller hearth; rotary hearth; rotating retorts; and miscellaneous special types.

Furnace Materials—For estimating comparative operating costs of different designs, it is safe to assume that firebrick linings will last for 2 yr. at temperatures below 1900°F., and for 1 yr. above 2000°F. This does not apply to door jambs, piers and bridgewalls, which will require additional patching. The life of metal parts when properly designed for stress, and for usual furnace conditions will be approximately as follows:

		Cast Iron	Alloy
Below 1400°F.	5 years	
1700°F.	12 months	3 years
1800°F.	5 months	2 years
1900°F.	1 month	1½ years
2000°F.	not used	½ year

Commonly used alloy analyses in the design of furnace parts include:

Furnace Temp., Below 1400°F.		Furnace Temp., Above 1400°F.	
Nickel, %	Chromium, %	Nickel, %	Chromium, %
25	20	68	18
18	8	60	12
8	18	38	18
..	28	35	15
..	18	30	10
		12	28
		11	25

Determination of Furnace Size*—The size of furnace required depends upon the amount of material to be heated per hour, the heating time required, the size of the pieces to be heated, and the amount of heat which can be liberated without excessive damage to the furnace. The efficiency and refractory life obtained, depend upon the correctness of the furnace size.

The heating time in the furnace depends upon the nature of the heating process. For the simple case of thorough heating, the time required may be estimated from such rules as 5 min. for each $\frac{1}{8}$ in. of thickness of flat plates of steel (heated from one side) and 20 min. per in. of diameter or round steel bars. These rules apply when the furnace temperature is above 1400°F. At 800°F. the time is increased about 100%, and below 800°F., it may require as much as three times as long to heat thoroughly as it does above 1400°F. The time required for heating varies also with the material to be heated. Brass requires about one-half as long as steel to heat and copper 40% as long. The above rules represent the minimum time in which the material will conduct heat to its interior and therefore, will not be greatly affected by variations in the difference between the furnace temperature and that of the material. The rules also assume that the material is fully exposed to the heat of the furnace. Piling of material in a furnace lengthens the heating time, which cannot be expressed numerically, but must be determined by actual trial. In addition to simple heating, there is frequently additional time required for holding at temperature.

The weight of material in the furnace at any time is the product of weight of material discharged per hour, multiplied by the heating time in hours. Knowing the weight and sizes of pieces involved, the area of the furnace can then be fixed. The width and length of the furnace to produce this hearth area are fixed by the method of firing to be used and by the method of handling material.

The life of a furnace at a given temperature depends upon the rate of heating, which may be expressed in pounds per square foot of hearth area per hour. The maximum allowable rate of heating steel is about 35 lb. per sq. ft. per hr. for underfired and overfired furnaces, 70 lb. for sidefired furnaces, and 100 lb. for direct fired furnaces. These are upper limits which should not be exceeded if long life of the furnace refractories is expected. The above rates are for heating mild steel, and may be about twice as great when heating brass, $2\frac{1}{2}$ times as great for copper, and 0.7 times as great for alloy steels. These maximum allowable rates should be used only for checking the calculation of size, because some shapes and sizes of pieces cannot be properly heated when piled in such a manner as to produce these rates.

Calculating Furnace Size—If a furnace is required to heat 20 pieces per hour weighing 30 lb. each and requiring a heating time of $\frac{1}{2}$ hr., the furnace must be large enough to hold $\frac{1}{2} \times 20 = 10$ pieces. If each piece requires an area of 2 sq. ft., the area of the hearth will be $2 \times 10 = 20$ sq. ft. for a single layer of pieces in the furnace. If the furnace is of the batch type, a size of 4 ft. wide x 5 ft. deep would probably be about right for convenient handling. Checking the rate of heating (20 pieces per hr. x 30 lb.) per 20 sq. ft. = 30 lb. per sq. ft. per hr. For this rate, an underfired furnace would be satisfactory, while for other methods of firing a smaller furnace could be used, if the pieces could be more densely piled without seriously interfering with the circulation in the furnace.

The allowable rate of heating, expressed in pounds of steel per square foot of hearth area per hour, varies according to temperature. At tempering temperatures of about 1000°F., the usual rate is about 25 lb. per sq. ft. per hr., compared to the allowable rate of 30 lb., given above for heat treating at 1500-1600°F. By means of fans for air circulation, this rate may be increased to 35 lb. in an electric furnace. At heat treating temperatures of 1500-1600°F., air circulation will not increase the rate of heating sufficiently to be worth while, because the amount of heat transferred by convection is small.

Economy of Furnaces—The heat input to a heating furnace is distributed in various ways, depending upon the type of furnace. Ordinarily, the heat balance includes useful heat to material; heat to conveyors, shoes, or pans; radiation and absorption to the furnace lining; radiation through openings; sensible heat in waste

*From, Combustion Furnace Section, by M. H. Mawhinney, Mark's Mechanical Engineers' Handbook, Third Edition, McGraw-Hill Co.

gases of fuel furnaces; and heat in unburned fuel in waste gases of fuel fired furnaces. Miscellaneous additional items include heat to water cooled parts, radiation from cars in car bottom furnaces when the car is out of the furnace, or conduction by metal parts extending out of a furnace.*

It is quite customary to line electric furnaces with a greater quantity of insulation than is used in fuel fired furnaces, on account of the higher cost of electric current per heat unit. However, because of the absence of waste gases in electric furnaces, this smaller amount of radiation appears as a greater per cent of the heat input.

Table III gives the average fuel economies for typical heating furnaces, expressed in B.t.u. per lb. of material heated in fuel furnaces, and in kw-hr. per ton for electric furnaces. The values given represent good operation at efficient rates of production, and are for operation without recuperators or other heat saving devices. To obtain the fuel consumption, divide the economy in B.t.u. per lb. by the lower heating value of the fuel under consideration from Table I. The values of Table III are typical figures and will vary for different furnaces.

Table III
Fuel Economies for Heating Furnaces

Operation	Average Temp., °F.	Average Economy Good Operation	
		Fuel B.t.u. per lb.	Electric kw-hr. per ton
Tempering—Batch type	1000	700	120

*Economies for carburizing furnaces are fuel per gross weight, including boxes and compound. The values will vary with depth of case.

*The method of calculating these various losses may be found in *Industrial Heating Furnaces*, by W. Trinks, and *Practical Industrial Furnace Design*, by M. H. Mawhinney, both published by John Wiley & Sons, Inc.

Furnace Atmospheres—The knowledge of this subject is at present in a stage of such rapid evolution, that it is difficult to express definite conclusions without fear of contradiction. Interest in the possibilities of atmosphere control for reduction and elimination of scale oxidation has been awakened by a recent flood of discoveries. This research has included, principally, the action of the several constituents of combustion gases on hot steel and methods of bright heating of ferrous and nonferrous metals without oxidation by the use of specially prepared gases introduced into electric or muffle furnaces. Several years will be required to digest and assort the amount of data recently published on these subjects.

Atmosphere in Fuel Furnaces—It has been generally understood for many years that the principal constituents of combustion gases are CO_2 , nitrogen, water vapor, and CO or O_2 . The proportions depend upon the degree of mixing and the relative quantities of fuel and air introduced into the burners. Several simultaneous publications in 1930 brought to general notice the fact that H_2 also exists in flue gases in quantity about equal to that of the CO content.

Since that time, extensive research has been carried on to determine the effects of furnace atmospheres, and a summary of the principal conclusions can be found under the heading "Furnace Atmospheres and Steel," by Clair Upthegrove in the American Gas Association Monthly for May, 1933.

In general, it has been found that the scaling, or oxidizing gases in a furnace atmosphere are CO_2 , water vapor, and O_2 , while the reducing constituents are CO, H_2 , and unburned hydrocarbons from the fuel. The scaling action of the atmosphere at any temperature and for any time of contact depends upon the relative proportions of these gases in the atmosphere. The so-called neutral atmosphere, where theoretically correct quantity of air is introduced with the fuel, resulting in a complete absence of O_2 or CO in the atmosphere, is a scaling atmosphere because the proportions of CO_2 and water vapor are high. To reduce the scaling of carbon steel to 50% of that resulting with this atmosphere, requires the excess of fuel necessary to give about 2% CO in the flue gases at 1700°F ., and about 14% CO at 2300°F . To eliminate scale in a combustion furnace is practically impossible. Sulphur in the fuel also increases the amount of scaling of steel.

In addition to scaling, the atmospheres of fuel furnaces frequently decarburize. Moist H_2 and water vapor are principally responsible, and where decarburization must be avoided, an oxidizing furnace atmosphere, with excess air, is the best method. Such an atmosphere is lower in CO_2 content, and in addition, the scale caused by such an atmosphere will inhibit decarburization.

Atmosphere in Electric or Muffle Furnaces—The atmosphere in these furnaces is normally air from the atmosphere which forms a heavy free scale on steel at all temperatures above about 1200°F ., the amount of scale depending upon the temperature.

So far it has been found impractical to operate direct fired fuel furnaces with sufficient CO and H_2 content to offset the scaling action of water vapor and CO_2 , so the developments in bright heating have been confined to electric and muffle furnaces. This is accomplished by maintaining a truly neutral atmosphere in the furnace or muffle, so that no oxidizing reaction between steel and atmosphere takes place. Such atmospheres include H_2 from electrolytic dissociation of water, dissociated ammonia, and mixed gases obtained from partial combustion of hydrocarbon gases. By the use of specially prepared gases, the carbon content of the steel can also be controlled.

Automatic Control of Atmosphere—The automatic control of atmosphere in fuel furnaces involves the control of fuel-air ratio and the control of furnace pressure. The methods of fuel-air control commonly used for fuel fired heat treating furnaces include the following:

1. The method of manual adjustment of fuel and air valves for high and low settings is used for two pipe burner systems, oil or gas fuel, and with two position control.
2. Proportioning valves depend upon constant ratio of fuel and air orifices at all settings and are used for two pipe burner systems, oil or gas, with two or three position and proportioning (multiposition) control.
3. High pressure gas burners or injectors, where gas automatically injects a constant ratio of air and flow of gas only is controlled; used with all kinds of control.
4. Low pressure proportioning systems for gas, where gas is reduced to zero pressure and air automatically inspirates a constant ratio of gas and flow of air only is controlled; used with all kinds of control.

With fixed fuel-air ratio, automatic pressure control is necessary to maintain constant furnace atmosphere on account of the variation of fuel rates. Unless a constant pressure is maintained at all times in the furnace, air will enter the furnace and cause an oxidizing condition. The pressure is a function of the openings in the furnace and the fuel rate. Therefore, to maintain pressure, the openings must automatically adjust themselves to the rate of fuel flow.

Comparative Costs of Fuels—In comparing the cost of operation, the major items for consideration are: 1. Charges on the investment; 2. labor; 3. maintenance; and 4. fuel. The first three items depend largely upon the construction of the furnace and the type of conveyor or other mechanism involved for handling. A true comparison of fuel cost must include a consideration of the percentage of heat lost in the flue gases. For example, all of the heat liberated in an electric furnace at all temperatures goes to heating the metal, the furnace lining, radiation through openings, and such losses. In contrast, a fuel fired furnace involves an additional loss in the flue gases leaving the furnace.

Table IV gives the amounts of various fuels which equal 1 kw-hr. of electric heat at different temperatures, after correcting for flue gas losses. The comparative cost is also shown in the table based on assumed fuel costs which are given. The B.t.u. equivalent of 1 kw-hr. used in this table is 3415.

Table IV
Comparison of Fuels

	Furnace Temp., °F.	Net B.t.u. per Unit	Cost per Unit, Cents	Units Equivalent to 1 kw-hr.	Cost Equivalent to 1 kw-hr. Cents

Blast furnace gas, cu.ft.....	1000	90	0.0023	57.0	0.131
	1500			79.4	0.183
	2000			126.5	0.290

The figures in Table IV afford a comparison of the cost of heating with various fuels, assuming the same furnace construction in all cases. In actual practice, more insulation is used on electric furnaces than on fuel furnaces, so that the relative cost of electricity with respect to other fuels is slightly less than is indicated by the table.

The cost of fuels is a guide in their selection, but should never be used alone to determine the best fuel for any given conditions. The relative convenience and cost of preparation must be carefully studied. Of even more importance is the kind of heating possible with various fuels, including accuracy of control, and nature of surface obtainable. The fundamental purpose of a furnace is to properly heat a given material, and frequently the savings from the use of a cheap fuel are quickly lost in the cost of material spoiled by improper heating.

Fuel to Heat Cold Furnace—It is often desirable to know the quantity of fuel required to heat a furnace from cold to operating temperature. This may be calculated from the data in Table V. These values are based on the usual practice

of firing hard at the start and cutting down the fuel rate as the furnace comes up to temperature.

Table V

Rate of heat liberation (B.t.u. fired per sq. ft. of interior per hr.) required to heat firebrick lined furnace to temperature in given time.

Hours to Final Temp., Ready for Operation	Operating Temp., °F.		
	1000	1500	2000
2	6000	12000
4	4200	6800	13500
6	3300	5100	8000
8	2700	4300	6000
10	2200	3800	5200
12	1800	3300	4800
14	1600	3000	4500

Furnaces lined with the so-called "light refractories", which are made to combine a part of the advantages of both firebrick and insulating brick, will heat up in about one-half the time required for firebrick, with the same rate of heat input.

The following illustrates the use of Table V for calculating the quantity of fuel oil required to heat a firebrick furnace with 1000 sq. ft. interior area, from cold to 1500°F. in 4 hr.

$$\frac{4 \text{ hr.} \times 6800 \times 1000}{140,000 \text{ B.t.u. / gal.}} = 194 \text{ gal. oil}$$

Operation of Oil and Gas Burners—There are several fundamental facts which should be kept clearly in mind when lighting furnaces equipped with oil or gas burners. For all fuel fired furnaces, observe the following rules:

1. Open all doors before lighting the furnace.
2. When lighting oil burners or gas burners of the blast (two pipe) type, turn the air on first, then the fuel.
3. When lighting gas burners of the low pressure proportional mixing type, always open the gas supply valve wide; all regulation of fuel is by the air flow and the ratio adjusting screw on the mixer.
4. When shutting off an oil burner, or a gas burner of any type, always shut off the fuel first.

Due to the rapid ignition of most gaseous fuels, there is generally little difficulty in keeping gas burners lighted. With oil burners, however, care must be taken when lighting. When the finely divided atomized oil strikes cold surfaces in the furnace, condensation takes place and separated carbon burning with insufficient air causes dense smoke. Small quantities of oil with excess air should be burned until the burner block becomes red hot to assist in the vaporization of the oil and to maintain ignition. A baffle in the form of a steel bar inserted from the outside and projecting in front of the burner will assist in lighting most oil burners, because it keeps the velocity of the atomized oil below that of ignition, and affords the mixture an opportunity to light before passing through the furnace chamber.

When lighting a furnace involving several burners, it is best to properly light one or two at a time, rather than to attempt to light all burners at once. The reason is that unburned combustion gases constitute an effective fire extinguisher and several improperly adjusted burners will interfere with the lighting of others.

A new furnace after construction should be slowly dried out with gradually increasing temperature to avoid spalling and cracking. This process should take two or three days, while the moisture in the brick and clay is slowly converted to steam and released without damage to the brick structure. In heating a large furnace to 2000°F., a good schedule of drying is as follows, although a considerable variation can be made: 10 hr. below 500°F.; 8 hr. below 1000°F.; 8 hr. below 1500°F.; and 8 hr. below 2000°F., giving a total time of 34 hr.

After the furnace has been heated to temperature and the doors closed, the total flue area should be partially closed until a pressure of about 0.01 in. water exists in all parts of the furnace. Temperature uniformity in the furnace may be regulated by closing the proper flues when regulating to the proper pressure. In general, the flues at hotter portions of the furnace should be closed to force more gas and heat toward flues left open in the colder portions of the furnace.

Liquefied Petroleum Gases

By George R. Benz*

Introduction—Liquefied petroleum gases for industrial use are available in two commercial grades, propane and butane. Commercial propane consists, essentially of propane and propylene, with very small amounts of ethane, butanes and butylenes. Commercial butane consists, essentially of butanes and butylenes, with small amounts of propane and propylenes. These fuels are manufactured at natural gasoline plants and refineries.

Properties of Liquefied Petroleum Gases—Liquefied petroleum gases and natural gas have similar combustion characteristics. Natural gas is composed principally of the paraffin hydrocarbons, methane and ethane. Liquefied petroleum gases are likewise composed principally of paraffin hydrocarbons. However, where obtained from refineries, olefin hydrocarbons are also present. Some of the most important and useful properties of commercial grades of propane and butane are shown in Table I. Table II shows comparative data for typical industrial gases and propane and butane.

*Engineer, Philgas Department, Phillips Petroleum Co, Detroit.

Storage and Vaporization—Propane and butane are shipped in special pressure type tank cars, tank trucks, and in small cylinders. Tank cars and tank trucks are unloaded, by pump or pressure differential, into the plant storage system. Plant storage tanks are constructed by fusion welding, in accordance with Section VIII, A.S.M.E. Unfired Pressure Vessel Code, and installed in accordance with rules and regulations of the National Board of Fire Underwriters, or other insurance or regulatory body having jurisdiction. Pressure type storage tanks are used, 80 lb. working pressure for butane, and 200 lb. working pressure for propane.

Propane and butane are piped about the plant as a gas, consequently require vaporization or gasification prior to distribution. This is accomplished by supplying the latent heat of vaporization and releasing the pressure. Vaporization is automatic, and in accordance with the plant fuel demand. In most propane installations, the gas is withdrawn from the vapor space above the liquid in the storage tank and passed into the plant piping, after passing through suitable regulators. When the fuel requirements are large, or when butane is used, a separate vaporizer is employed.

¹A.G.A. Handbook "Combustion."

²Phillips Petroleum Co.

Undiluted propane gas is piped about the plant at either low or high pressure, the exact pressure being determined by the type of burner equipment.

Undiluted butane gas may be piped about the plant at low pressure, provided the temperature does not fall below the dew, or condensation point. If high pressure

gas is required, butane must be diluted or partially mixed with air prior to distribution. Dilution with air lowers the dew point.

Combustion Equipment—Table II shows that the rate of flame propagation (speed of combustion) of propane and butane is low, but comparable to that of natural gas. This "slow burning" characteristic permits a lower air-gas mixture velocity through burner ports or nozzles without back firing, as well as allowing the operation of certain types of burner equipment with a lower manifold pressure, with corresponding greater range of "turn up" and "turn down".

The comparative efficiency of various gaseous fuels is in direct relation to the available heat of the gas, all factors of furnace construction and operation being equal. The available heat of a fuel is the difference between the gross B.t.u. value and the amount of heat contained in the products of combustion at the temperature under consideration. The available heat of both propane and butane is high, and is at 2000°F. approximately 50% of the gross B.t.u. value. Propane and butane contain no noncombustible constituents such as nitrogen, carbon dioxide, or water vapor.

Tables I and II show important combustion data for propane and butane, the most important to the engineer being the products of combustion, ultimate CO₂, air required for combustion, rate of flame propagation, flame temperature and average composition. Propane and butane are generally used through the various types of air-gas combustion equipment and burners.

Fuel Oil

By J. E. Hamilton,* R. T. Goodwin† and R. C. Brierly†

Fuel oil, as the term is broadly used, covers a wide range of products ranging from those similar to kerosene down to fairly heavy residua.

Grades of Fuel Oils—Standardization has led to a generally accepted division of fuel oil into five classes based on several physical properties. The Commercial Standard, (CS12-38), gives the property limits of the various grades as shown in Table I.

The first three grades in Table I are the domestic heating oils. In general, Grades 1-3 are distillates and Grades 5 and 6 are residual products or blends of residua and distillate from the crude oil refining process.

Industrial fuel oil, unless purchased under a service contract containing definite performance provisions, may meet all the specification tests, but may differ from previous deliveries. The product being manufactured may be contaminated, furnace refractories may fail much more rapidly than before, smoke problems may be increased, or fouling may develop in some part of the oil handling systems. Any of these things, and others, may happen due to changes in the oil which are not apparent in the tests which have been developed.

Properties of Fuel Oils—The characteristics of fuel oil which are of interest are:

Physical characteristics:

1. Viscosity
2. Gravity
3. Flash point
4. Fire point
5. Physical impurities
 - (a) Water
 - (b) Grit and fibrous materials
 - (c) Solid bodies
6. Pour point

Chemical characteristics:

1. Composition
2. Heat value
3. Uniformity
4. Stability
5. Acidity
6. Impurities, such as sulphur

Viscosity—Viscosity is that property of fuel oil which determines its resistance to flow. It is measured by an instrument, the viscosimeter, which in all its different types comprises a means for determining the time in which a measured quantity of oil at a standard temperature goes through a tube of standard dimensions. The instrument commonly used in the United States is the Saybolt of which there are three instruments of different flow tube dimensions. The Saybolt Universal viscosimeter is usable for most lubricating oils and for fuel oils in the upper range of the domestic heating types. In practice, the Saybolt Universal viscosimeter is used up to flow period of between 500-1000 sec., at which point the Furol viscosimeter is applicable. Since viscosity varies with temperature, the principal requirement of any viscosity test is maintenance of the oil under test at specified temperature. Most tests are made at the following standardized temperatures: Saybolt Universal, 32°F. and 100°F.; and Furol, 77°F. and 122°F.

The principal direct effects of viscosity on utilization are in handling the fuel oil and in atomizing at the burners. Viscosity alone being considered, the only upper limit for practical utilization is the ability of the equipment to raise the temperature of the oil to a point where it will flow and atomize. Any lower viscosity limit is acceptable except that better construction of joints and seams is needed to prevent leakage with the extremely fluid types.

The upper limit must be determined by the location and facilities of the plant. In general, it can be stated that Grade 5 fuel oil is satisfactory for use in almost any system where the temperature between the tanks and the preheaters can be maintained above 32°F. and in the preheaters can be raised to at least 125°F. Grade 6 fuel oil can be used in any system where the temperature before the preheater can be maintained above 100°F. and after the preheater can be delivered to the burner at a temperature of 240°F. For fuel oil of viscosity above the upper limit of Grade 6 the system should be so designed that the temperature before the preheater can be maintained sufficiently high to prevent the viscosity exceeding

Table I
Commercial Standard Specifications*
 (CS12-38)

Detailed Requirements for Fuel Oils
 Adopted May, 1938

Grade ^b	Flash Point, °F.	Min. Max.	Pour Point, °F.	Max.	Water and Sedi- ment, %.	Carbon Residue, %.	Ash, %.	Distillation Temperatures, °F.				Viscosity Seconds—	
								10% Point Max.	90% Point Max.	End Point Max.	Min.	Saybolt Universal at 100°F. Max.	Saybolt Furol at 122°F. Max.
No. 1 Fuel Oil—A distillate oil for use in burners requiring a volatile fuel.	100		165	15 ^c	Trace	0.05 ^d on 10% residue		410		560 ^e			
No. 2 Fuel Oil—A distillate oil for use in burners requiring a moderately volatile fuel	110		190	15 ^c	0.05	0.25 ^f on 10% residue		440	600				
No. 3 Fuel Oil—A distillate oil for use in burners requiring a low viscosity fuel.	110		230	20 ^c	0.10	0.15 straight		675	600 ^g		55		
No. 5 Fuel Oil—An oil for use in burners requiring a medium viscosity fuel	130				1.00		0.10				60	40	
No. 6 Fuel Oil—An oil for use in burners equipped with pre-heaters requiring a high viscosity fuel	150				2.00 ^h							300	45

^aRecognizing the necessity for low sulphur fuel oils used in connection with heat treatment, nonferrous metal, glass and ceramic furnaces and other special uses, a sulphur requirement may be specified as follows: Grade No. 1 and 2, 0.05% max., Grade No. 3, 0.75% max., Grade No. 5 and 6 no limits. Other sulphur limits may be specified only by mutual agreement between the buyer and seller.

^bIt is the intent of these classifications that failure to meet any requirement of a given grade does not automatically place an oil in the next lower grade unless in fact it meets all requirements of the lower grade.

^cLower or higher pour points may be specified whenever required by conditions of storage or use. However, these specifications shall not require a pour point lower than 0°F. under any conditions.

^dFor use in other than sleeve type blue flame burners, carbon residue on 10% residue may be increased to a max. of 0.12%. This limit may be specified by mutual agreement between the buyer and seller.

^eThe maximum end point may be increased to 590°F. when used in burners other than sleeve type blue flame burners.

^fTo meet certain burner requirements the carbon residue limit may be reduced to 0.15% on 10% residue.

^gThe minimum distillation temperature of 600°F. for 90% may be waived if A.P.T. gravity is 26 or lower.

^hWater by distillation, plus sediment by extraction. Sum, max. 2.0%. The maximum sediment by extraction shall not exceed 0.50%. A deduction in quantity shall be made for all water and sediment in excess of 1.0%.

500 Saybolt-Furol-Seconds and after the preheater to permit reducing the viscosity to at least 200 Saybolt-Universal-Seconds.

Gravity—Gravity of fuel oil is measured by an arbitrary scale which is related to the specific gravity. In the United States the scale used is that known as A.P.I. (American Petroleum Institute) which is based on specific gravity using the moduli:

$$\text{For oils lighter than water, A.P.I.} = \frac{141.5}{\text{sp.gr.}} = 131.5$$

$$\text{For oils heavier than water, A.P.I.} = 145 - \frac{145}{\text{sp.gr.}}$$

Gravity is measured by hydrometers graduated to the A.P.I. scale. Since the hydrometer reading is dependent upon displacement of oil whose gravity is being measured, the weight of the oil displaced will vary with the coefficient of expansion of the oil. Gravity is ordinarily measured at whatever temperature the oil may happen to be, coincidentally measuring that temperature, and then correcting the gravity to a standard temperature of 60°F. by the use of tables published by the United States Bureau of Standards.

At present fuel oils of the industrial grades are obtainable at gravities ranging from 3 or 4 A.P.I. (1.021 sp.gr.) to 25 or 30 A.P.I. (0.876 sp.gr.). The heavier the oil the greater its B.t.u. content, per unit volume; hence, since oil is commonly sold on a volumetric basis, it is highly advantageous to obtain oil of the lowest gravity (highest sp.gr.) if it has other acceptable characteristics.

Flash Point—Flash point is the temperature at which the oil first emits sufficient gas to cause a momentary, nonsustained flame when subjected to standard flame. Standardized instruments for measuring flash point are either the closed cup type or the open cup type. In general the open cup readings are about 20-30° higher than the closed cup which is the instrument usually used for specification tests. The temperature of the oil to be tested is raised in the instrument until the first nonsustained flame appears when a lighted taper having a flame of standard size is applied near the surface. Flash points may vary from slightly above atmospheric temperatures to well above 200°F. For kerosene and domestic heating oils many states have laws limiting flash points to not less than some figure which possibly averages around 100°F. Fire due to low flash point must be initiated by a flame. For fuel oils above the domestic range normal limits have always been either 150 or 175°F. as a minimum. It is considered that a minimum limit of 150°F. is entirely satisfactory.

Fire Point—Fire point is measured by increasing the temperature above the flash point until a sustained flame of at least 30 sec. duration is initially produced. Fire point has never been specified for fuel oil. Its only possible connection with utilization is in its relationship to the ease of starting a fuel oil fire. Practical methods of starting fire are such that any fuel oil can be ignited and once ignition has taken place it will continue. There is no benefit to be derived from further consideration of fire point.

Water as an Impurity—Water can enter fuel oil either through condensation or contamination. This can occur either before or after the oil is delivered to the storage system. It was previously accepted as satisfactory to test water by gravitational separation. Acceleration of operation was obtained by use of a centrifuge with a standard radius, speed of rotation, and sample test tube. This method was undoubtedly satisfactory for fuel oils of the straight run types where the water was interspersed through the body of the oil as free water and where the oil has a sp.gr. of less than 0.95. For close determination the method is wholly unsuitable for many cracked oils or for a majority of oils whose gravities are close to or less than that of water. For any oil a true determination of water content can be obtained by a distillation test.

It is possible for water to be present in very minute globules up to as much as 5% if highly emulsified. It is very improbable that a purchaser need protect himself against any limits beyond about 5%. Up to this amount water might be present without being readily discernible.

Water reduces the fuel value of the oil, not only by the lesser volume of actual oil but also by the furnace loss in vaporizing the water. It is customary in specifications not to exceed 1% of water at the contract price and not to exceed 2% with a price adjustment for the water in excess of 1%.

Grit and Fibrous Materials as Impurities—It is possible for fuel oil to pick up gritty and fibrous materials during the refining process. All such foreign material can be removed by straining. There are no standard methods of test for determining the presence of these materials, but their possibility should be obviated by installing at some point in the system an adequate strainer to remove all sizeable foreign bodies.

Solid Bodies as Impurities—Solid bodies in the fuel oil may be of a mineral nature which became entrained in the same manner as grit, or they may be particles of carbon formed in the oil during the refining process. Protection against non-combustible impurities may be obtained by a crucible burning test where combustion is carried to completion and the increase in weight of the crucible after burning represents the weight of the noncombustibles in the sample. The test is difficult to control.

Pour Point—Pour point is the lowest temperature at which oil will flow or pour. It is a function of temperature. Pour point is measured by reducing the temperature of a small quantity of the oil in a test tube until it will no longer flow. Pour points run from well below zero to in the order of 80°F., or higher, pour point of straight run residual oil will run considerably higher than those which are residual of cracking processes.

In practice large bodies of oil do not congeal at as high a temperature as will a small sample of the oil in a test tube. There is practically no need for specifying any pour point limitation where the oil in storage will not be subjected to temperature below freezing. Where storage tanks of fuel oil are exposed to atmospheric temperatures in the winter, it would be advisable to have a maximum pour point limit about 10% higher than the expected minimum temperature of the oil.

Chemical Composition—The two principal constituents of fuel oils are hydrogen from 8-20% by weight and carbon from 80-92% by weight on a water-free basis. Other elements, which are impurities in the pure hydrocarbons, may be present. Sulphur which may be in amounts from a trace to nearly 5% is the most common impurity. Other possible constituents, rarely present in amounts over 0.5%, are the halogens, metals, and salts.

It is possible that some additional impurities may enter the fuel oil as a contaminating residue from the refining process. Some refineries use ammonia, lime, sulphuric acid and probably other reagents in different phases of treatment which may be added to the residual fuel oil.

Since the thermal value of hydrogen oxidation is greater than that of carbon, the more valuable fuel per lb. is that with the higher percentage of hydrogen. However, since United States practice has been standardized on volumetric units for sale of fuel oil, the advantage is reversed as has been mentioned above because the high-hydrogen oils are lighter. For practical purposes, the carbon-hydrogen ratio is sufficiently well established by the sp.gr. measurement (which increases with the percentage of carbon) that hydrogen content may be neglected.

When heating steel in an open chamber, it should be remembered that hydrogen burns to H₂O and gives a harsh cutting flame.

Heat Value—Heat value is a measure of the amount of energy which is obtainable from the oil when burned. There have been a number of empirical formulae developed for determining the calorific value by using other measurable characteristics. Inchley's formula based on the ultimate analysis is:

$$\text{B.t.u. per lb.} = 13,500 \text{ C plus } 60,890 \text{ H.}$$

The Naval Boiler Laboratory formula is:

$$\text{B.t.u. per lb.} = 17,751 \text{ plus } 53.4 \times \text{the A.P.I. gravity at } 60^\circ\text{F.}$$

Either of the above formulae will give results close enough for practical purposes. The more accurate method is by measurement in a bomb calorimeter.

Uniformity—Fuel oil which is a residual product from the same process will be practically homogeneous throughout except for the slight deposition of sludge settling in storage. The sludge may be greater with some cracked residues than with normal straight run residue. It should offer no difficulties in service if the suction line on the storage tank is so arranged that the suction is above the sludge line.

It is possible to blend a viscous residue with a low viscosity distillate and obtain a very unsatisfactory product although theoretically, they should be exactly correct as to viscosity. The reason appears to be that there is such a thing as incompatibility between some residues and some distillates. Except in cases of incompatibility,

any blend properly made will remain uniform indefinitely, that is, there is no tendency for the two constituents to separate once they have been well blended.

Stability—This term as here used applies to the freedom from chemical change of the fuel oil due to conditions of pressure, temperature, or age, either in storage or in the system until burned. For a straight run product there is little probability that any chemical change will occur in practice. Maximum temperatures attained prior to ignition are several hundred degrees below cracking temperature. In storage at moderate temperatures it would take an extremely long time to cause any of the chemical changes which are accelerated by heat. However, for cracked fuel oils it has been found that, even though the oil has been subjected to cracking temperatures, it is not necessarily stable at temperatures encountered in the fuel oil system. It is not definitely known whether this change is a chemical or a physical change.

Acidity—The normal opacity of fuel oil makes the litmus or other color reaction change inapplicable. It is possible by setting up a suitable arrangement to run distilled water through the oil (known as washing) and then test the recovered water for acidity. This test should reveal any extreme acid condition.

Sulphur as an Impurity—Sulphur in a fuel oil is probably rarely present in the free state. It is normally present in the form of hydrogen sulphide or other sulphur derivatives. Any fuel oil whose content of hydrogen sulphide is apparent from the odor on delivery should be rejected.

Sulphur present in any form will, after combustion, be present as sulphur dioxide. Sulphur dioxide in the gases of combustion will cause no difficulty until it is cooled below the boiling point of water. If the gases of combustion are released to the atmosphere at temperatures well above 212°F. so that they disperse before condensation, no destructive concentration of sulphurous or sulphuric acid can be encountered. The greatest difficulty is due to pockets in the combustion or flue spaces where gases of combustion may collect and condense. Since such spaces will also collect soot, the sulphur dioxide dissolved by the condensate will form sulphurous or sulphuric acid which will be absorbed by the soot and is highly corrosive to contiguous metal. Proper design or frequent thorough cleaning will minimize this difficulty.

If the equipment for heat treating of metals is so designed that the gases of combustion themselves impinge directly upon the metal being treated it is possible that sulphur contamination will occur. Also, it is detrimental to a number of alloys, especially heat and corrosion resisting alloys of the high nickel-chromium type and to Chromel-Alumel thermocouples. Sulphur may be present in fuel oil in quantities as high as 5%, but such a percentage is rare. As fuel, this reduces the heat value slightly. Where the heating equipment requires direct contact between the gases of combustion of the fuel oil and the product, it is recommended that a sulphur limit of 0.5% be specified.

Equipment—Where the location of a plant is favorable to the use of fuel oil, the equipment should be made, or modified, to fit all probable kinds of fuel oil. This should certainly be done in installing new equipment. In most cases old equipment can be modified to permit utilization of any possible fuel oil without serious difficulties.

Fuel Storage System—If local regulations will permit, the fuel storage system should be located at a reasonably high elevation above the furnaces. The total tankage should be divided into four tanks or four subbatteries of tanks so that one can at all times be in use, one standby for use, one empty, cleaned and awaiting delivery, and one being cleaned. It is advisable to receive fuel oil only into clean tanks and not to mix it with any oil remaining from previous deliveries.

All fuel oil tanks should be equipped with steam heating coils of sufficient outside surface to maintain the oil in the tank at a temperature of at least 80°F., using saturated steam at whatever pressure may be available. For plants located where extreme winter weather conditions may be encountered, a saving in fuel will probably compensate for insulation on the tanks.

Each tank should have a pipe connection at the lowest point in the tank for use in cleaning or draining water and sediment.

Fuel Supply System—Connections to the tanks should be so made that suction in the tank will be above the sludge line. All connections should be so manifolded that any tank can be separately connected. In calculating the pipe size, allow a considerable margin to reduce flow restrictions. In calculating flow losses, each fitting and 90° bend may be equivalent to from 50-100 feet of piping. Properly

designed fittings, welded into the pipe, will reduce these figures considerably. A double basket or similar strainer should be installed on the discharge side of the pump. However, strainers are also installed on the intake side of the pump.

Pumps of the screw type are successfully used even in cases where there is not a positive pressure on the supply side. A priming pump is used in these cases. Motor driven geared pumps are commonly used. These are of the positive displacement type and the excess oil is returned to the tank through a relief valve set at the desired operating pressure. Any pump, if properly designed, will handle fuel oil if its viscosity (either before or after heating) is not greater than 700 Saybolt-Furol-Seconds.

In the event of fire or fuel oil system breakage, the supply line entering each building should be provided with a quick closing valve operable from either inside or outside the building.

Burning Equipment—The fire installation consists of the service pump, fuel oil preheaters, air registers, atomizers (commonly called burners), and fans or other draft forcing apparatus.

Fuel oil atomizers are of four general types: Mechanical pressure, mechanical centrifugal, air, and steam. The amount of work performed by an atomizer is definite and can be calculated in ft.-lb.

Mechanical pressure atomizers require high pressure piping systems and preheaters. Preheaters are usually operated on exhaust steam. They reduce the viscosity of the fuel oil to a point where droplets of fuel oil can be forced by pressure through the passages of the sprayer plate or tip and plug which forms the working portion of the device. The small passages in the sprayer plate or tip and plug are more apt to be clogged by sediment than the relatively larger ones of other type atomizers.

Centrifugal atomizers form mist-like fogs of fuel oil by means of a cup rotating at high speed together with a blast of air passing around its periphery. Moving parts tend to increase upkeep, and they occupy considerable space on the furnace, principally because air intermixing registers are required.

Steam and air atomizers are similar in construction. In both cases, the oil drooling at low pressure from an orifice is caught by a blast of air and steam and shattered into the form of finely divided particles, principally by impact. All air and steam atomizers may be subdivided into two principal types: The outside mixing and the inside mixing. Oil, in the former case, is reduced to fine particles outside the metal portions of the atomizer itself, and in the latter case, air or steam surrounds and entrains the oil particles, carrying them through an orifice which may be designed in such a manner that practically any shape of flame can be obtained. Thus, the use of a circular orifice will provide a conical flame; a horizontal slot, a "fish tail" flame.

The best type of atomizer to be used depends upon conditions existent in the plant.

Air Mixing—It is necessary that the atomized oil be thoroughly mixed with air in sufficient quantities for complete combustion. The oil and air mixture must be intimate; this is a function of the air register operating in conjunction with the atomizer. The air may be drawn into the furnace through the register or apertures either by the natural or forced draft.

On heat treating and drop forging furnaces and furnaces of this type, the air for combustion is usually supplied through the burner without the use of air registers.

The design of the combustion space should provide a "target" wall or baffle for the flame to play on so that it will not impinge directly on the metal being heated or the brickwork. The furnace dimensions should be sufficient to allow full combustion of the oil in the furnace. With cracked fuel oils these dimensions must be greater than for straight run oil. For additional information on industrial heating furnaces and types of burners see page 262.

Properties of Refractories

The properties of commercial refractory materials may differ because of impurities, location of the source of raw materials, bonding materials, and manufacturing processes. As the readers' interest may be with both the commercial and pure refractories, Tables I, II, and III give the chemical and physical properties of the commercial, and Table IV of the pure refractories.

Table I
Chemical Properties of Commercial Refractories

By F. H. Norton*

Material	Theoretical Composition	Reaction with Basic fluxes ¹	Reaction with Acid fluxes ¹	Resistance to Oxidation	Resistance to Reduction
Alumina (fused)	Al ₂ O ₃	Fairly rapid with fluid slags. Slow in cement kilns	Fairly slow	Good	Not affected
Carbon	C	Slow	Slow	Low above red heat	Not affected
Chromite	FeO.Cr ₂ O ₃	Slow	Slow	Low above red heat	Reduced to ferrochromium at high temp.
Fireclay	2SiO ₂ .Al ₂ O ₃	Rapid	Slow except at high temp.	Good	Not affected
Forsterite	2MgO.SiO ₂	Fairly slow	Fairly slow	Good	Not affected
Graphite	C	Slow	Slow	Good	Not affected
High alumina (diaspore)	Al ₂ O ₃ .H ₂ O	Fairly rapid with fluid slags. Slow in cement kilns	Slow at low and medium temp. Rapid except at low temp.	Good	Same as alumina
Magnesite	MgO	Slow	Rapid except at low temp.	Good	Reduced to Mg at high temp.
Mullite	2SiO ₂ .3Al ₂ O ₃	Rapid	Fairly slow	Good	Not affected
Porcelain (refractory)	2SiO ₂ .3Al ₂ O ₃	Rapid	Fairly slow	Good	Not affected
Silica (fused)	SiO ₂	Rapid	Slow	Good	Not affected except at high temp.
Silica (ganister)	SiO ₂	Rapid	Slow	Good	Same as fused silica
Silicon carbide	SiC	Fairly rapid	Slow	Fair above red heat	Not affected
Spinel	MgO.Al ₂ O ₃	Slow	Fairly rapid	Good	Not affected
Zircon (electrically fused)	ZrO ₂ .SiO ₂	Fairly rapid	Slow	Good	Not affected except at high temp.
Zirconia (electrically fused)	ZrO ₂	Fairly slow	Slow	Good	Forms carbides at high temp.

*Prof., Mass. Institute of Technology, Cambridge, Mass.

The slag resistance of a refractory is influenced by its physical as well as its chemical properties. Therefore, a dense nonporous structure without flaws is desirable.

Pyrometry*

Pyrometry deals with the measurement of all temperatures above about 950°F. The principal methods of pyrometry are the thermoelectric, the optical, and the radiation methods. The thermoelectric and the total-radiation methods can easily be extended to temperatures below 950°F.

Thermoelectric Pyrometry—Thermoelectric pyrometers may be satisfactorily used for measuring temperatures up to about 3000°F.

Principle of the Thermoelectric Pyrometer—In 1821 Seebeck discovered that if two dissimilar wires are joined together at both ends and one junction is heated, an electromotive force (emf.) or voltage is generated in the circuit. This phenomenon is called the thermoelectric effect. The discovery led to the development of the thermoelectric pyrometer, a simple form of which is illustrated by Fig. 1. It consists of a millivoltmeter connected to two wires of different metals, the other ends of which are joined together and placed in a furnace. The two wires of different metals joined together at one end constitute the *thermocouple*, one wire being the positive element and the other the negative element. The millivoltmeter is an instrument to measure the emf. or voltage generated.

Some thermocouples consist of two elements in the form of wires while others consist of a wire element within a tubular element.

In the thermoelectric circuit shown in Fig. 1 there are three junctions as follows: The junction of the two wires inside the furnace, often called the "hot junction," now generally referred to as the "measuring junction"; and the two junctions between the elements of the thermocouple and the copper wires connecting them to the millivoltmeter, A and A_1 . Although there are two such junctions in the arrangement shown in Fig. 1, the pair is commonly treated as a unit and often called the "cold junction," now more generally referred to as the "reference junction." Since we are concerned altogether with high temperatures, we shall adhere to the terms, "hot" and "cold," as they can lead to no misunderstanding.

At each of these junctions an emf. is generated which varies with the temperature of the junction, and the algebraic sum of these three emf.'s is the emf. measured by the millivoltmeter. If the temperature of the cold junction pair is maintained constant, then the resultant emf. as measured by the millivoltmeter varies only with the temperature of the hot junction.

Thermocouple Materials—The number of metals and alloys suitable for commercial use in thermocouples is rather limited for they must be resistant to oxidation, recrystallization, melting, and contamination at high temperatures; they must develop an emf. high enough to be measured without the use of delicate apparatus; and finally, they must be reproducible and readily obtainable in uniform quality.

The different combinations of materials in common commercial use for thermocouples are: Platinum vs. the alloy 87% platinum plus 13% rhodium; platinum vs. the alloy 90% platinum plus 10% rhodium; "Chromel" vs. "Alumel"; iron vs. "constantan"; and copper vs. "constantan." The last three pairs are commonly referred to as "base metal couples."

The useful life of a thermocouple depends not only on the maximum temperature to which it will be subjected, but also on the atmospheric conditions to which it will be exposed.

Platinum vs. platinum-rhodium thermocouples may be used up to a temperature of 3000°F., but they are easily contaminated and must be suitably protected at all times. Continuous subjection to temperatures above 2800°F. is not recommended.

There is no completely satisfactory material for long service in reducing gases. Stainless steel (iron-chromium-nickel alloy) is being used to a limited extent paired with Chromel, but the couple has not been standardized by the instrument companies.

The Chromel-Alumel thermocouple will generally be more satisfactory than the iron-constantan in oxidizing atmospheres at 1200-2200°F. Chromel-Alumel may be

*The article on thermoelectric pyrometers was originally prepared by a Subcommittee on Pyrometry consisting of Kirtland Marsh, Chairman; R. P. Brown, F. A. Faust, S. C. Horn, W. T. Morgan and C. O. Fairchild. The article on optical and radiation pyrometry was originally prepared by F. H. Dike. All of the material on pyrometry has been revised for this Edition by a Subcommittee consisting of R. B. Sosman, Chairman; P. H. Dike, W. G. Martin, F. W. Paine, W. F. Roeser and H. T. Wensel.

used intermittently up to a temperature of 2400°F. Its emf. is subject to change when the wires are exposed to a reducing atmosphere.

The iron-constantan thermocouple is not recommended for continuous use in air at temperatures above 1400°F. At this temperature, No. 8 gage wire of either element of the couple will last about 1000 hr. in air. The couple will generally have a longer life and be more satisfactory than Chromel-Alumel in a reducing atmosphere up to 1800°F.

The copper-constantan thermocouple is satisfactory for continuous use up to 700°F. and for intermittent use up to 1000°F.

The life of any base metal thermocouple will be relatively short when exposed continuously to temperatures above 2200°F. Alternately reducing and oxidizing conditions are especially detrimental to any base metal thermocouple.

Construction of Couples—The hot junctions of all thermocouples should be welded except in the case of base metal thermocouples for use at comparatively low temperatures (below 1000°F.), when the hot junction may be silver soldered. Borax is a satisfactory flux for silver soldering any base metal thermocouples or for welding iron-constantan. Fluorspar is better for Chromel-Alumel thermocouples. Plenty of flux should be used.

Use an oxy-gas or oxy-hydrogen flame and no flux for welding platinum thermocouples. Greater mechanical strength at the hot junctions of base metal thermocouples can be obtained by twisting the two wires together for about two turns before making the weld.

When base metal thermocouples have burned out or have become so contaminated that they give too low readings, destroy them so that they can not be used again by mistake.

When platinum thermocouples have become contaminated and give incorrect readings, it is often possible to do something toward their restoration by annealing with an electric current in air and cleaning with fused borax. Silicon, calcium, magnesium, and perhaps other elements, can be removed in this way, but iron can never be completely removed. The necessary equipment and procedure for reconditioning platinum thermocouples is described in Bureau of Standards Technologic Paper No. 170. It has recently been found that movement of the rhodium in the alloy is responsible for some of the change, and there is no remedy for this type of deterioration.

Cold Junctions—Every thermoelectric pyrometer is calibrated for a particular cold junction temperature, generally 0°F., 32°F., or 75°F. During subsequent use the cold junction need not necessarily be maintained at that particular temperature as long as the actual temperature is known, for it is possible to compensate for the difference between the actual cold junction temperature and that for which the instrument was calibrated.

It is generally more practical to compensate instrumentally for different cold junction temperatures than to maintain them at the particular temperature for which the pyrometer was calibrated. However, it is highly desirable to eliminate frequent variations in the cold junction temperature.

Extension Leads—Unless the two wires forming the thermocouple are long the cold junctions will be so close to the furnace that they will be subject to extensive temperature variations. As it is desirable to locate the measuring instrument some distance away from the furnace, and as it is often impractical to make the thermocouple long enough to reach to the instrument, lead wires or "extension leads" are used to connect the thermocouple to the instrument.

If in Fig. 1 the leads are of copper, the cold junction is close to the furnace at A. If, on the other hand, the extension leads consist of a pair of wires of the same material as the thermocouple, or of some less expensive pair of materials having the same thermoelectric characteristics as the thermocouple pair, the cold junction will be located not at the furnace but at the binding posts of the instrument, B, a position of more constant temperature.

Fig. 1

Fig. 2

Fig. 1—Simple thermoelectric pyrometer circuit.

Fig. 2—Thermoelectric pyrometer with the cold junction in a well in the ground.

The extension leads of base metal thermocouples are usually made of the same materials as the thermocouple wires, but in the case of platinum-platinum-rhodium thermocouples a copper lead is connected to the platinum-rhodium wire and a special copper-nickel lead to the platinum wire. Although the temperature-emf. relation of the copper, copper-nickel extension lead wire is practically the same as that of platinum-platinum-rhodium thermocouples, the individual lead wires are not identical thermoelectrically with the thermocouple wires to which they are attached and, therefore, the two junctions where the leads are attached to the thermocouple should be kept at the same temperature. This means that special care must be taken that this pair of junctions is not heated unsymmetrically. Such precautions are unnecessary in the case of base metal thermocouples where each lead and thermocouple wire to which it is attached are the same material. For similar reasons, the point of connection between the extension leads and thermocouple should be limited in temperature to 200°F.

Extension leads for a thermocouple of one pair of materials should not be used with a thermocouple of a different pair of materials.

The positive and negative lead wires, identified by color of insulation or otherwise, must always be connected respectively to the positive and negative elements of the thermocouple. If in doubt as to the identity of the positive and negative wires of extension leads, test them with a millivoltmeter or potentiometer. It is possible to have the extension leads wrongly connected to the thermocouple and also wrongly connected to the instrument, in which case the instrument will read up-scale, yet read wrong. An up-scale reading is no guarantee of correctness in the set-up. A safe way to connect the circuit is first to connect the leads alone to the instrument, twist the other end of the leads together and heat with a match. The instrument should read up-scale. Then connect the leads to the thermocouple, let the lead terminals cool, and heat the couple junction. The instrument must again read up-scale; if it reads down, reverse leads at the couple, not at the instrument.

There are a few simple methods of using extension leads to remove the cold junction to a position of constant temperature and for making one cold junction serve several thermocouples.

The arrangement shown in Fig. 1 with extension leads to remove the cold junction to the indicator, is the simplest, but the cold junction is still subject to the variations in room temperature, which will introduce errors in the reading unless the indicator is equipped with an automatic cold junction compensator.

Fig. 2 shows extension leads used to locate the cold junction in a well in the ground. This is a construction now seldom used but it serves to illustrate conveniently the character of the thermocouple circuit. The cold junction well consists of a piece of pipe with a pointed plug welded into one end to aid in driving it into the ground. If the well is 8 ft. deep or more and located away from steam and water lines, sewers, and furnace flues, the temperature at the bottom will be practically constant from day to day even though it may change a little with the season of the year.

In any pyrometer system the thermocouple and leads must be kept dry. The cooler temperature at the bottom of a cold junction well may cause moisture to condense in the pipe so that it is advisable to use an inner pipe in the well. The inner pipe should be capped or welded closed at the bottom end and the top end sealed with paraffin or compound.

The arrangement shown in Fig. 2 can be easily understood by considering a closed thermoelectric circuit without any measuring instrument. The positive and negative elements of the couple and the positive and negative extension leads are joined together at the hot and cold junctions respectively, and then, at any point along its length, the positive lead is cut so that the instrument can be connected in series with the two junctions. It should be noted that although both wires connected to the instrument are of the positive material, the one connected to the positive binding post on the instrument is connected to the positive element of the thermocouple and the one connected to the negative binding post leads ultimately to the negative element of the thermocouple. The same emf. reading would be obtained if we were to cut the negative lead for insertion of the instrument.

Cold Junction Compensation—If the cold junction temperature is not maintained constant, but is allowed to take the temperature of the air, as it is in most pyrometer installations, correction or compensation must be made for this fluctuating temperature.

If the measuring instrument (see later paragraphs for description) has no

manual or automatic device for compensating for the cold junction temperature, the correction can be made with the aid of tables of emf. vs. temperature for the thermocouple which is being used. It is incorrect simply to add an air temperature correction to the reading of the instrument without knowing the temperature-emf. curve.

With a millivoltmeter having no automatic cold junction compensation but with a scale reading in degrees, variations in the cold junction temperature can be compensated for by making the zero or open circuit position of the instrument pointer on the scale agree with the actual cold junction temperature. This can be done by means of the "zero adjustment" provided. This adjustment should be checked at frequent intervals because the cold junction temperature may have changed, or the zero setting of the pointer may have been accidentally disturbed.

With a millivoltmeter equipped with an automatic cold junction compensator, the zero position of the pointer should agree with a specified temperature on the scale or with the actual cold junction temperature, depending upon whether the compensator is electrically operated or is mechanically operated as in the case of the bimetallic spring, "Breguet Spiral," on the moving coil. In either case, follow the manufacturer's instructions.

With a potentiometer, a manually operated or an automatic cold junction compensator is generally provided. If it is manually operated, the dial should be adjusted to agree with the actual cold junction temperature at frequent intervals.

The temperature sensitive element of the compensator and the cold junction of the thermocouple should be kept close together and so shielded or wrapped that the temperature of the one will always be the same as that of the other. The reader is referred to the manufacturers for detailed descriptions of the different types of compensators in common use.

Fig. 3 illustrates the use of extension leads when a number of thermocouples are connected to a distant instrument equipped with an automatic cold junction compensator. Instead of extending the extension leads from each thermocouple all the way to the instrument, they are extended only to a centrally located common zone box and a single auxiliary couple is extended from the common zone box to the temperature sensitive element of the automatic cold junction compensator. The cold junction for the system is at B.

This arrangement is solely for the purpose of reducing the amount of extension leads required and is advantageous only when it results in a reduction in the total cost of installation.

Relation of Emf. and Temperature—Until recent years, each manufacturer of thermoelectric pyrometers had his own source for thermocouple alloys and his own curve for the relation of emf. to temperature. The platinum metal thermocouples were the first to be standardized, and tables of emf. vs. temperature for both the 10% rhodium and the 13% rhodium couple have been accurately determined by the National Bureau of Standards. These tables are now accepted as standard by most if not all of the manufacturers of pyrometers in the United States.

Next came Chromel-Alumel. These two materials are trade marked nickel alloys. Their composition and properties are capable of being kept under good technical control. The Bureau of Standards, having found that the alloys can be reproduced to specifications, has published a standard table which is now in general use by the pyrometer manufacturers.

Iron-constantan and copper-constantan are not yet standardized. Constantan is no longer a trade marked name, but applies to a limited range of copper-nickel alloys containing a little manganese. Pure iron is difficult to make, and the wire

Fig. 3

Keep These Cold Junctions Close to the Temperature Sensitive Element of the Automatic Cold Junction Compensator

Fig. 3—Connections between several thermocouples and a distant instrument equipped with an automatic cold junction compensator.

actually used is about 99.9% iron with small amounts of various elements which influence its thermal emf. There is no difficulty about getting reproducible pure copper, but a minor complication arises from the fact that slightly different constantan alloys have been used with copper and with iron. Recent studies at the Bureau of Standards on the constantan group of thermocouple alloys have shown that the L. H. Adams' table for copper-constantan represents reproducible material, and that this same constantan can be combined with a low metalloid iron wire to give an emf. curve reproducible to 0.8%. Certain pyrometer manufacturers use constantan alloys that depart from this curve by several per cent, but they use other trade names for their couples so no confusion is likely to result.

Table I contains the accepted data for the platinum alloy and Chromel-Alumel couples, together with those data for constantan couples which the Bureau of Standards considers most representative of materials readily available. At the head of each column, in naming the couple, the positive element is named first.

Other Thermocouples—Many other combinations have been used in thermoelectric pyrometry, but none has attained the general acceptance of those listed in Table I. The use of iron-chromium-nickel alloys has already been mentioned. Molybdenum vs. tungsten is useful at very high temperatures in hydrogen or vacuum. Graphite vs. tungsten and graphite vs. silicon carbide have been given some trials in open hearth steel furnaces and ladles.¹

Protection Tubes—One of the reasons why certain materials have come into common use for thermocouples is that they are reasonably stable thermoelectrically when heated in a clean oxidizing atmosphere. The standards of performance which are generally accepted for the various combinations of thermocouple materials are based upon their performance in air. Although it has not been shown that a reducing atmosphere, in itself, necessarily contaminates or alters the thermoelectric properties of thermocouple materials, it is nevertheless generally observed that exposure

¹See G. R. Fitterer, A New Thermocouple for the Determination of Temperatures Up to at Least 1800°C., *Trans., A.I.M.E.*, 1933, v. 105, p. 290.

of thermocouples to such atmospheres is accompanied by contamination or change in the chemical composition which seriously alters their thermoelectric properties. In order, then, to obtain the best performance of thermocouples, it appears necessary to maintain them in an atmosphere having essentially the same composition as air. Consequently the selection of a proper protection tube, which will protect the thermocouple from vapors, fumes, or furnace gases, is sometimes as important as the selection of the thermocouple materials.

Contamination results from causes such as the following:

(1) Metals (solid, liquid, or vapor) coming into contact with the thermocouple materials and altering their chemical composition.

(2) Furnace gases and fumes coming into contact with the thermocouple materials. Sulphur and sulphur compounds are particularly deleterious.

(3) Materials normally stable in an oxidizing atmosphere coming into contact with the thermocouple material in a reducing atmosphere. One common cause of contamination, which is serious in the case of rare metal thermocouples, is the reduction of silica (usually present in insulating and ceramic protection tubes) to silicon which readily combines with the thermocouple materials.

(4) Preferential oxidation and reduction of base metal alloys when these are exposed alternately to oxidizing and reducing atmospheres. This results in a gradual change in chemical composition, because all the elements which comprise an alloy cannot be expected to oxidize and reduce at the same rates under all conditions.

Many types of protection tube are required in order to meet all needs. In many cases, the conditions under which thermocouples are used are such that two tubes are required to provide the desired protection. For instance, a primary tube of porcelain or fused silica may be placed inside of a secondary tube of metal, silicon carbide, or fire clay. The primary tube of low volatility is intended to provide the imperviousness to gases at high temperatures, and the secondary tube provides the resistance to thermal and mechanical shocks and to corrosion.

In thus providing protection for the thermocouple, however, one should not lose sight of the fact that a thermocouple can perform its function only when the conditions of heat transfer are such that the measuring junction will attain or at least approximate the temperature to be measured. When a tube of large cross section or more than one tube is used, particularly if the tubes have a high thermal conductivity, it should be carefully considered whether the depth of immersion is sufficient to insure that the temperature of the thermocouple junction is reasonably close to the temperature to be measured. Short heavy tubes may cool the junction so much that the indications are comparatively worthless.

Platinum to platinum-rhodium thermocouples are particularly susceptible to contamination and should be protected by ceramic tubes which are impervious to gases and vapors at all operating temperatures. If furnace gases are not present, metal protection tubes are usually sufficient protection for base metal thermocouples. The oxide coatings on the thermocouple wires are fairly effective in protecting the wires from contamination by metallic vapors. Metal tubes which provide sufficient protection in an oxidizing atmosphere may be entirely unsatisfactory if large amounts of furnace gases are present.

The primary ceramic tubes which meet most requirements of stability and imperviousness to gases are: Highly refractory porcelain, sometimes called "Sillimanite" or "Mullite," for temperatures up to 2800°F. Fused silica for temperatures up to 1900°F. in an oxidizing atmosphere. Pyrex glass for temperatures up to 1100°F.

The secondary or metal tube most suitable for a particular application depends to a large extent upon the type of corrosion encountered. Nickel tubes are useful above 2100°F. Tubes of nonscaling alloys such as nickel-chromium and nickel-chromium-iron are suitable for many applications at temperatures up to 2000°F. Tubes of iron and steel are suitable for numerous applications up to 1500°F. Calorized wrought iron is impervious to certain gases and meets certain needs up to 1800°F. Fire clay, silicon carbide, and graphite meet certain requirements of secondary tubes at temperatures above the useful limit of metal tubes.

Numerous other types of secondary tubes have been developed for specific purposes. Information regarding the best type of tube for any particular purpose is usually available from the pyrometer manufacturer.

Insulators—Except at the hot junction where the two wires should be welded together the two elements of a thermocouple must be electrically insulated from each other. Fire clay or porcelain beads and even asbestos for low temperatures, are satisfactory for base metal thermocouples. However, for platinum thermocouples, clean porcelain beads or tubing should be used.

The insulation on the thermocouples should be maintained intact because if the wires come in contact with each other another junction may be formed which will cause the indicator to register some other temperature than the temperature of the hot junction of the thermocouple.

Terminal Heads—Terminal heads for thermocouples are not absolutely necessary because the leads can be soldered, brazed, or welded directly to the elements of the thermocouple, but they simplify installation and replacement of thermocouples, keep contaminating dirt and dust out of the protection tube and provide a good connection between thermocouple and leads. It is recommended that they be used.

Measuring Instruments—The instrument for measuring the emf. of the thermocouple may be either *indicating* or *recording*. Either an indicating or a recording instrument may also act as a *controller*.

An indicating pyrometer simply shows the instantaneous temperature on a dial. A recording pyrometer produces a graphic record of the temperature on a moving sheet of paper graduated in minutes, hours, or days. Such a record serves to show whether the furnace has been maintained at the proper temperature at all times. A graphic record of the temperature is of particular value for manual control, in that it shows the trend or the rate of change in temperature and so enables the operator to anticipate conditions and to control the furnace more intelligently. Graphic charts filed away are often of value at some later date when a question arises as to the quality of materials produced on a certain day.

Most indicators and recorders can be grouped in two general classifications: (1) millivoltmeters or deflection type instruments, and (2) those operating on the potentiometer principle. In addition, there are some that embody features of both types.

Millivoltmeters—A millivoltmeter consists of a coil of wire suspended between the poles of a permanent magnet so that the coil is free to move. A pointer is attached to the coil and moves over a scale graduated in millivolts or in degrees. The terminals of the thermocouple are attached to the terminals of the coil, and the emf. generated in the thermocouple circuit sends a current through the coil, causing it to deflect in the magnetic field. The magnitude of the deflection depends upon the current through the coil which in turn depends on the emf. generated by the thermocouple and the resistance of the circuit.

Millivoltmeters are calibrated to indicate temperature correctly when connected to a thermocouple and leads of a certain total resistance. The indications of the instrument will change if the resistance of thermocouple plus leads is other than that specified on the instrument. In principle, inaccuracy in a millivoltmeter pyrometer due to changes in the thermocouple can be corrected, at least over a reasonable range near the critical operating temperature, by adjusting the resistance of the circuit, a simple method of adjustment which is possible only in the case of millivoltmeter type instruments. Rheostats for this purpose are seldom provided, however, and this method of correction is not recommended as a standard procedure.

Since the design of a millivoltmeter is a compromise between sensitivity, ruggedness, and resistance, no specific recommendations as to the proper value of internal resistance can be made. However, it is safe to say that much less than 100 ohms will probably make the instrument subject to appreciable errors with change in temperature and that much over 600 ohms will probably require that the instrument be more delicate than is necessary.

Potentiometers—A potentiometer, shown diagrammatically in Fig. 4, is a source of known values of emf. against which the unknown emf. from a thermocouple may be balanced. The primary source of the emf. may be a dry cell, a liquid primary cell, or a storage cell. The dry cell is the most used.

The standard current to make the drop in emf. across the fixed resistance of the slide wire agree with the millivolt scale attached to it is obtained by adjusting the rheostat until the emf. drop across the standard cell coil is equal to the emf. of the standard cell, as indicated by a zero deflection of the galvanometer with the switch on the standard cell point. This

Fig. 4—Diagram of potentiometer circuit.

adjustment needs to be made at frequent intervals because the voltage of the dry cell or other current source constantly changes.

The emf. from the thermocouple is then balanced against the emf. drop across a portion of the slide wire by adjusting the position of the movable contact until the galvanometer deflection is zero.

The galvanometer, like the millivoltmeter, is essentially a movable coil between the poles of a magnet, but is usually capable of detecting smaller variations of current. It has no measuring function, such as the coil has in the millivoltmeter, but acts solely by deflecting from its zero position. The measuring is all done by the moving contact on the slide wire.

The standard cell is the source of known constant emf. It has practically no current capacity so its terminals should never be connected together except through a resistance of several thousand ohms. A standard cell may be badly damaged if subjected to temperatures below 0°F. or above 120°F. It undergoes small permanent changes of the order of 0.01-0.1% at temperatures below 40°F., and it is therefore desirable not to expose it to temperatures below freezing.

The reading of a potentiometer pyrometer is independent of the resistance of the thermocouple circuit except as an increase in the resistance will decrease the sensitivity of response of the galvanometer. The higher the resistance of the thermocouple circuit the greater is the change in emf. required to produce a perceptible deflection of the galvanometer. It is therefore advisable to keep the resistance of the thermocouple circuit or length of extension leads within reasonable limits. This is particularly true in the case of a recording potentiometer where an appreciable deflection of the galvanometer pointer is required to operate the automatic balancing mechanism.

Since only the response of the galvanometer is affected by a change in resistance of the thermocouple circuit, a potentiometer cannot be adjusted to correct for variations from the standard emf. of a thermocouple by changing the resistance of the thermocouple circuit. By increasing or reducing the value of the standard current through the slide wire by the same percentage that the emf. generated by the thermocouple is above or below the standard emf. for that type of thermocouple, the reading of the potentiometer will be corrected for the discrepancy in the emf. This adjustment is practical only when the potentiometer is equipped with a scale to indicate the percentage deviation from the standard value of the current through the slide wire and is applicable only to a potentiometer connected to a single thermocouple.

In general, it is advisable to replace the thermocouple rather than tamper with the indications of the instrument.

Portable Potentiometer—The adjusting mechanism for the moving contact of the slide wire of a potentiometer may be either manual or automatic. Manual adjustment is found in various types of *portable indicating potentiometer*. These instruments can be made rugged and are little subject to change in calibration and are, therefore, satisfactory for use with a standardized thermocouple for calibrating other thermoelectric pyrometers. Their cold junction compensation is always electrical, consisting of supplementary coils that can be connected in series with the slide wire, and the compensation adjustment is usually manual. For a particular type of thermocouple, such as the Chromel-Alumel, the compensation may also be made automatic, and consists then of supplementary coils of a metal whose resistance changes at the proper rate with the temperature of the instrument.

The portable indicating potentiometer may be used with any type of thermocouple if the main dial is calibrated in millivolts and if it is provided with a manually operated cold junction compensator calibrated in millivolts.

The main dial and the compensator dial can be calibrated in degrees of temperature for a particular type of thermocouple but both dials should also be calibrated in millivolts if the instrument is to be more generally useful.

Automatic Potentiometer—In the past 20 years there has been an extensive development of the automatic potentiometer. In this instrument the galvanometer, on deflecting from zero, actuates a motor mechanism of some kind which adjusts the slide wire contact until the galvanometer deflection is again zero. In one group of instruments the galvanometer coil carries a pointer, like that of the millivoltmeter, and this pointer interferes mechanically with a mechanism having a periodic motion. In another group the pointer is replaced by a mirror and a reflected beam of light which acts in various ways through a photoelectric cell as a medium.

In most automatic potentiometers the standard current in the slide wire must

be adjusted manually with the aid of the standard cell. In a few types this adjustment, also, is made automatically at regular intervals. One type records the actual value of the slide-wire current at fixed intervals, thus making the record complete even though the adjustment may have been neglected. In one type dependence is placed upon the constancy of characteristics of a small ammeter, in place of the standard emf. cell.

Installation of Thermoelectric Pyrometers—Thermocouples—Locate the hot junctions of the thermocouples where they will measure the desired temperature. Close up the openings around the protection tube to prevent hot gases from blowing out around the terminal head and to keep cold air from being drawn in around the thermocouple.

Make the opening in the furnace large enough so that a second thermocouple may be inserted alongside the furnace thermocouple for calibrating purposes but keep the extra space plugged up when not in actual use.

Determine the proper depth of immersion and mark the thermocouple or protection tube or both so that they can always be returned to the same position. It is well to have the thermocouple clamped in the protection tube and the protection tube clamped to the furnace so that the depth of immersion cannot be changed accidentally.

Be sure that positive leads are always connected to positive leads or the positive element of the thermocouple, and negative to negative except at the hot junction. If a positive lead has been erroneously connected to a negative, a thermo junction will have been formed which will cause a deflection of the instrument pointer when the junction is heated. Any suspected splices or connections can be tested in this way.

It is generally worth while, although not absolutely necessary, to install the leads from the thermocouple to the instrument in conduit.

All connections in the thermocouple circuit, except where binding posts are provided, should be soldered. Insist that the soldering be done with a soldering iron rather than with a torch. A poor joint made with an iron is generally apparent, whereas a torch made joint may appear to be good and still be poor.

Because of the alloys used, some extension leads are difficult to solder, and it may be necessary to scrape and tin each individual strand in order to assure that all strands are well soldered together. All strands must be well soldered.

Never use soldering acid as this may set up galvanic action and cause serious errors in the readings. Lump or powdered rosin or a solution of rosin in alcohol is the best for copper, but is not satisfactory for most extension lead material. A good soldering paste can be used if the joint is well washed with gasoline (or better, carbon tetrachloride which is noninflammable) after the soldering is completed.

Disconnect all instruments before ringing out any circuits with a battery or magneto and bell, because the instruments are not built to stand even battery voltage.

In a millivoltmeter installation, measure and record the resistance of each thermocouple circuit to make sure that it agrees with the manufacturer's specifications. A comparison of these records with subsequent measurements may reveal the source of some trouble.

Instruments—For the greatest return on the investment, locate the recorder where the furnace operator can observe it and make use of the information it gives.

The principal enemies of the indicating and recording instruments are: (1) Dust, (2) vibration, (3) excessively high temperatures, (4) excessively low temperatures. The instrument should be mounted on a substantial support as free from vibration as possible and so located that it will not be mechanically damaged, nor subjected to currents of air, direct radiation from the sun or hot surfaces, or extreme variations in temperature. A special pyrometer booth is often advisable.

Measurement of Temperatures with Thermocouples—A thermocouple measures only the temperature of its hot junction. Since a thermocouple has appreciable mass, time is required for the temperature of the hot junction to change. In a furnace whose temperature is changing, a thermocouple will indicate a temperature lower or higher than the actual temperature of the furnace depending on whether the latter is rising or falling. This is called temperature lag. The extent of such lag will depend upon the mass of the thermocouple and protection tube around it and upon the rate of change of furnace temperature.

Heat may be conducted to or away from the hot junction from a hotter or to a colder portion of the thermocouple and so cause the temperature of the hot junction to differ from that of the medium immediately around it. If the depth of immersion of the thermocouple in a furnace, that is, the length of that portion

within the furnace chamber, is insufficient, heat will be conducted away from the hot junction and reduce its temperature below that of the medium around it. To correct such a condition, increase the depth of immersion of the thermocouple in its protection tube an inch or two at a time until the pyrometer shows no further increase in temperature. During this procedure the furnace temperature must be maintained constant by means of another stationary thermocouple, or otherwise, and sufficient time must be allowed for the temperature of the hot junction of the thermocouple to reach equilibrium. The error in indication of furnace temperature by a thermocouple with insufficient depth of immersion will not necessarily be a constant error but may vary from hour to hour and day to day and so cannot be determined and allowed for in subsequent readings. It is better to buy a thermocouple longer than necessary than to have too little depth of immersion.

Flame in contact with the hot junction will cause the thermocouple to indicate a temperature higher than the average furnace temperature, and flame in contact with any part of the thermocouple may cause high readings and will certainly shorten its life. Contact with flame may frequently be avoided by inserting the thermocouple through a hole in the rear or a side wall rather than through the arch.

The temperature of material in a furnace can sometimes be estimated by comparing the brightness of the material with that of the hot end of the thermocouple. Have the hot end of the thermocouple as close to the work as possible and in such a position that both can be observed through a peek hole in the door. Be sure that neither work nor thermocouple are licked by any flame and that light from a hot flame-licked surface or combustion chamber does not cause either to appear hotter than it really is. When the work and hot junction are of equal brightness as closely as can be determined by eye, the temperature of the two will be the same to within possibly $\pm 10^\circ\text{F.}$, provided that both have dull absorbent surfaces which will not reflect light from hotter walls or flame.

Pyrometer Troubles—Pyrometer troubles can be divided into two classes, those external to and those within the instrument.

The details of design of instruments in use today are so varied that it is impractical to attempt a discussion of possible troubles within the instruments themselves. Some instruments are sealed by the manufacturer and in case of trouble within the case of these instruments they should be returned to the manufacturer for repair.

Other instruments, particularly recording and some control instruments, require occasional cleaning or adjustment by the user and accordingly those parts are made accessible. A book of instructions is furnished by the manufacturer with such instruments, so in case of trouble, consult the instruction book and proceed as directed. If the trouble cannot be eliminated, consult the manufacturer. In some instruments unit parts such as galvanometer systems and selector switches can be removed from the instrument and returned to the manufacturer, thus eliminating the necessity of returning the entire instrument.

Troubles external to the instrument can generally be eliminated by the user if the cause of the difficulty can be located. The following paragraphs enumerate some of the troubles which may be encountered and tell how to locate them.

I. Instrument Does Not Respond Properly to Change in Temperature of Thermocouple—(a) *Burned Out Thermocouple*—One element of the thermocouple may be completely oxidized or broken. This should be apparent from examination.

(b) *Broken Connection*—A wire may have come loose from a binding post or one of the leads may have broken at a soldered connection or elsewhere. The first should be apparent from a visual examination but the second may require that the instrument be disconnected and the circuit rung out with a battery or magneto and bell. If the circuit external to the instrument is found to be complete and the thermocouple in good condition there may be an open circuit in the instrument. This can be checked by applying an emf. from a potentiometer or another thermocouple to the binding posts of the instrument in question. Check all battery connections and sliding contacts. If the trouble is definitely located in the instrument, call in the manufacturer or return the instrument to him.

(c) *Faulty Selector Switch*—If a selector switch is used, the trouble may be in the switch in which case the instrument should respond properly when the thermocouple leads are connected directly to the instrument.

(d) *Short Circuit*—Make sure the leads or thermoelements have not become short circuited in the terminal head of the thermocouple. A short circuit may exist between the instrument and thermocouple. Disconnect the instrument and thermocouple and ring out the circuit which should be open.

II. Instrument Reading Is Erratic—The reading of the instrument may vary up and down the scale or if a selector switch is used the instrument may show one reading at one time and a different reading at another even though the furnace temperature has not changed.

(a) *Loose Connection*—Make sure that all binding posts and other connections are tight, that all sliding contacts are clean, and that the thermoelements are not loose or broken at the weld or elsewhere. If the weld at the hot junction is suspected, pinch it with a pair of pliers while it is still hot and note if the instrument reading changes suddenly. The leads may be broken at some point and still make intermittent or poor contact, in which case pulling or shaking the leads may locate the defect.

(b) *Faulty Selector Switch*—The switch contacts may be poor due to dirt or loose parts and this should be revealed by operating the switch. Tighten all parts, clean thoroughly, and if the contacts appear to have been greased supply a thin coating of fresh vaseline. If the switch is completely enclosed, not built for ready opening, a service man should be called or the instrument returned to the manufacturer.

(c) *Fault in Instrument*—Test for an open circuit in the instrument as described in Section I (b). In the case of a millivoltmeter the instrument pointer may be dragging on the scale. Some part of the moving system, or in the case of a potentiometer some part of the galvanometer such as the coil or a fiber of insulation on the coil, may be making contact with some part of the instrument, or a loose piece of magnetic material on one of the magnet poles. Rap the instrument case sharply with the knuckles and note if the pointer jumps to another position and remains there. It is sometimes possible to dislodge the obstruction by repeatedly causing the pointer to deflect clear across the scale. This can be done by intermittently connecting the instrument to a potentiometer or to a thermocouple hot enough to cause full scale deflection.

If the pivots of the moving coil of a millivoltmeter have become dull, there may be enough friction to cause the pointer to stop short of the actual temperature. Rapping the instrument case with the knuckles will generally cause the pointer to move to nearly the correct temperature. This trouble can only be corrected at the factory.

III. Instrument Reads Low—(a) *Zero and Cold Junction Settings*—Check the zero and cold junction settings as instructed by the manufacturer. If automatic cold junction compensation is provided, check the setting and adjustment of the compensator.

(b) *Battery Current*—If a battery is used in the measuring circuit, check the battery current.

(c) *Deteriorated Thermocouple*—The thermocouple may have deteriorated by oxidation or otherwise to such an extent that a lower than normal emf. is generated. Try a new thermocouple.

(d) *Wrong Thermocouple*—If a thermocouple which generates an emf. other than that for which the instrument is calibrated is connected to the instrument, it will read incorrectly; that is, a Chromel-Alumel thermocouple connected to an instrument calibrated for iron-constantan thermocouples will produce low readings.

(e) *Increased Lead Resistance*—Some of the individual wires in stranded leads may have broken or been poorly soldered or the thermocouple may be badly oxidized. Disconnect the instrument and measure the resistance of the external circuit. If it is materially higher than originally, replace the thermocouple and if still high look for trouble in the leads.

(f) *Short Circuit Through High Resistance*—A short circuit may be through low resistance, as in the case of good electrical contact between the two elements of the thermocouple or it may be through high resistance as in the case of a poor electrical contact between the elements of the thermocouple or leads. If the first case, the instrument reading will be much lower than the actual temperature, while in the second case the reading may be only a little lower than the correct temperature. Examine the thermocouple and all readily accessible points where such a condition might exist. If this fails, disconnect the thermocouple and instrument and measure the resistance which should be infinitely high. If an ohm meter is not available, try ringing through from one lead to another with a magnet.

A high resistance short circuit may be caused by dampness of the insulation on the leads. Moisture on some insulating materials may set up a galvanic action and cause the instrument to read too high. The previous use of soldering acid may cause the same effect.

(g) *Fault in the Instrument*—The calibration of the instrument may have changed. This can only be determined by a recalibration as described later.

A high temperature around the instrument would tend to make the instrument read low but generally not enough to be detected except by a recalibration.

If dry batteries are used in or around the instrument, moisture on the paper covers may cause a high or low reading. Note if the reading changes when the batteries are separated from each other and insulated from their support with a piece of glass.

IV. Instrument Reads High—(a) *Zero and Cold Junction Settings*—See Section III (a).

(b) *Faulty Standard Cell*—If the standard cell in a potentiometer has been damaged or has deteriorated, its voltage may be low and a low value of the standard current in the potentiometer circuit will result. This will cause the instrument to read high. Try another standard cell. Never test a standard cell with a voltmeter.

(c) *Wrong Thermocouple*—See Section III (d). A 13% alloy platinum-rhodium thermocouple connected to an instrument calibrated for 10% alloy platinum-rhodium thermocouples will produce a high reading.

Recalibration of a Thermoelectric Pyrometer—Comparison Method—The most satisfactory method of checking the calibration of a thermoelectric pyrometer is by comparison with another thermoelectric pyrometer of known accuracy such as a portable indicating potentiometer and a calibrated thermocouple. It is well to have two calibrated thermocouples, one to be kept as a primary standard and used only for rechecking the calibration of the second which is used for checking the calibration of the furnace pyrometer.

During the calibration, the hot junction of the standard thermocouple should be maintained in intimate contact with the hot junction of the furnace thermocouple in order to assure that they will be at the same temperature. In the case of base metal thermocouples, it is often advisable to bind them together with wire which will not contaminate the couples and will resist the furnace temperature. Insert both thermocouples in the same protection tube, making temporary use of a larger tube if necessary so that both will be equally lagged. Do not try to calibrate a thermocouple in one protection tube with a standard couple in another tube. If both thermocouples cannot be inserted in the one protection tube, use a larger diameter protection tube or insert them in the furnace without any protection tube. Remember that a Chromel-Alumel thermocouple should not be subjected to a reducing atmosphere for any extended length of time. Platinum thermocouples should never be inserted in a furnace without a protection tube, not even during calibration.

Have the furnace thermocouple at the same depth of immersion as in use, for if the thermocouple is contaminated the error in the reading may vary with the depth of immersion.

During calibration, the furnace temperature should be maintained as nearly constant as possible, but it is generally better to have a gradual increase or decrease in temperature than to have the temperature rising and falling as is often the case in an automatically controlled furnace. Substitute manual control if possible, or else lag the thermocouples to such an extent that the fluctuations in furnace temperature do not affect the temperature of the couples.

After both thermocouples have come up to temperature equilibrium, comparison readings may be made. Take several readings on each instrument at intervals of several minutes to make sure that a steady state has been reached.

If the instrument is found to be in error, it may be owing to one of the conditions mentioned under "Pyrometer Troubles," Section III. "Instrument Reads Low," or Section IV. "Instrument Reads High." All of these possibilities should be investigated before it is concluded that the calibration has changed.

If it is definitely decided that the calibration has changed, the trouble may be in the thermocouple or in the instrument. Try a new thermocouple and if that does not improve the situation the trouble is probably in the instrument, in which case it will have to be returned to the maker or a correction applied to the reading.

The correction to be applied can be determined by calibration at several temperatures throughout the critical operating temperature range of the furnace. If this is not possible, determine the correction at one point by calibration and use a percentage correction at other temperatures, that is, if a correction of $+10^{\circ}\text{F.}$ at 1000° has been determined, use a correction of $+5^{\circ}$ at 500° and a correction of $+15^{\circ}$ at 1500° . These corrections may not be quite correct but they will be better than none.

Calibration by the Freezing Point Method.—This is the method used by the National Bureau of Standards and a few well equipped laboratories for making primary calibrations of thermocouples. The proper procedure involves considerable technique and careful attention to details, and except in a few limited cases is not recommended for the majority of pyrometer users. Those interested in this method of calibration are referred to "Bureau of Standards Technologic Paper No. 170," and to "Methods of Testing Thermocouples and Thermocouple Materials," Bureau of Standards Research Paper, RP768, 1935.

Automatic Temperature Controllers—It is beyond the scope of this article to discuss the application of automatic temperature control equipment or even to describe the many and varied mechanisms that have been applied to thermoelectric pyrometers to enable them to control as well as indicate and record temperature.

An automatic temperature controller consists of: (1) A measuring instrument such as a millivoltmeter or potentiometer with its thermocouple; (2) an operating mechanism such as a chopper bar, contactor, or relay, including in some cases the driving motor; (3) a fuel valve, or for electric furnaces a device for altering the current.

The principal types of controls in common use are: (1) On and off; (2) 2-position; (3) 3-position; (4) throttling (various kinds); (5) multiposition follow up; and (6) floating. This classification of the various kinds of control is based on the manner in which the heat supply is automatically adjusted in response to the departure of the temperature from the control point. The characteristic action of types 1 and 2 is alternately to change the heat supply to high and low values as the temperature oscillates about the control point, with the result that the normal record is a wavy line if the recorder is sufficiently sensitive to detect the changes. With the other types the heat supply is changed only when the departure from the control point has reached a definite value, depending upon the width of the so-called neutral zone of types 3 and 5, or the width of the dead zone or limit of sensitivity in types 4 and 6.

On-and-Off Control—This type requires the least expensive equipment and is most generally used for electric furnaces. The results obtainable are satisfactory in most cases if the pyrometer is sensitive, if the lag is not too great, if only small oscillations of temperature are permissible, and if the "on" value of the power is not too great for the temperature selected. In many cases where only one nonadjustable source of power is available it is selected to be adequate for heating up and is too great for best results when the furnace is up to temperature. However, pyrometers are available that will control to a few degrees under such conditions.

Two-Position Control—The same pyrometric equipment is used either for on-and-off or 2-position control. The only difference between the two types is that in 2-position control the heat supply does not shut off completely when the temperature is high. In the latter case, generally selected for gas or oil firing, the fuel valve and in some instances the air valve working with it are operated back and forth to adjusted high and low limits, selected according to variations in demand and heat supply which must be provided for. It is not necessary that the gas-air ratio of the valves be correct through the full range, but only at and near the limits selected. However, in this type it is sometimes difficult to maintain the furnace atmosphere within the narrow limits of composition required.

Three-Position Control—This type of control can be applied only with equipment selected for this purpose and not with the on-off or 2-position controllers. The minimum required for electric heating is: Two voltages or two heating elements; two contactors; and possibly two relays. In these instances the third "position" is all power off. There are two principal advantages of this type over on-off control. If it is necessary to control at a temperature well below the maximum attainable with all power on, then an intermediate setting will improve control. For continuous processes, however, where a high heat is not essential for heating up, the 3-position is little better, if at all, than 2-position, in accuracy of control. In this type of control the neutral zone is always fairly wide because if it is narrow the rising or falling temperature traverses it so rapidly that the effect is the same as 2-position control, and probably less accurate.

Throttling Control—Equipment for this type of control for fuel fired furnaces consists in holding the valves at the setting required for the temperature selected, moving them only when the temperature changes and then only enough to stop the change and bring the temperature back to the control point without hunting. By hunting is meant oscillation of temperature with throttling control. Special equip-

ment is, of course, necessary, and is selected only when the apparatus has a large heat capacity or is so designed that the temperature of the thermocouple will lag seriously.

Multiposition Follow-Up—This type of control can be described for the present purpose as 3-position control with the limits fairly narrow and means for shifting the neutral zone to take care of changes in heat supply or demand, and the principal adjustment has to do with the width of the neutral zone. Detailed instructions are generally provided for this type of controller.

Floating—This type of control is applicable only where the lag is small and where the heat supply and demand never vary rapidly. Ordinarily no adjustments are required. When properly applied the accuracy obtainable is comparable with that of 2-position control with the two valves of heat set close together, but generally lag is sufficient to noticeably decrease the ability to maintain the correct temperature.

Installing and Starting Up Controllers—It is important to mount the controllers in locations relatively free from vibration. Not only will the accuracy of control generally be improved, but in some cases the wear on the control equipment will be lessened. Vibration-proof mountings are available for all types.

In the original installation of a controller it is important to test it as an indicator or recorder before connecting the power for the control circuits and to see that it is indicating correctly. Having done this the control circuit may be completed and the power cautiously applied either by interposing a lamp or low capacity fuse temporarily in the circuit or by momentarily closing the power switch. It is now necessary to check the polarity of connections to see that heat is turned on for a low temperature and off for a high temperature, and with 3-position control that the intermediate heat is applied when the control point is moved to coincide with the indicated temperature. So far the tests can be readily made without actually turning on the heat, but by observing the operation of relays, contactors, or valves, except with suppressed scale instruments, in which case it is necessary either to move the indicating pointer or carriage up to the control point or to stand by until the lowest temperature on the scale has been reached. In any case during the first

heating up, it is important that the operator stand by until the temperature has reached the control setting to determine that the heat is properly turned off and that all signal and safety devices are correctly wired. It is not necessary to do all this checking at a high temperature, but it is nevertheless advisable to watch the controller until the desired temperature has been reached.

Control Circuit Wiring—Except in the simplest cases control circuits should be wired according to a diagram furnished by the manufacturer or carefully designed beforehand. While the circuits are not particularly complicated there are many different arrangements, only a few of which will be described here. All of these circuits

Fig. 5—Wiring diagrams for automatic control circuits. A. "On and off" controller for electric heater or solenoid valve, not for relay or contactor unless specified; B. 2-position controller with rheostat for small furnace; C. 2-position controller; D. 2-position controller with 2 heating units; E. 2-position controller with tapped transformer, "C" always on "H" or "L"; F. Principle of 2-position controller and 3-wire relay; G. Principle of 3-position controller connection; H. 3-position controller with reversing motor with a 3-position and limit switches; I. 2-position controller and 3-wire relay, common line; J. 2-position controller with 3-wire relay, separate control line.

have many features in common. It is general practice to mark one of the terminals with a *C* for "common." In the simplest case of on-off control there will be one other terminal marked *L* for "low" and when the temperature is low the controller closes a connection or contacts between *C* and *L*. These two terminals alone suffice not only for on-off control but 2-position control with a rheostat or double heaters in an electric furnace, or for the solenoid valve with adjustable limits. In many cases, however, a third terminal is required which is usually marked *H* for "high" and connection is made between *C* and *H* when the temperature is high. In some controllers, *C* is always connected to either *L* or *H* while in other controllers, *C* is disconnected when the temperature is at the control point, in which case we have a 3-position controller. However, for some types of circuits or controllers 3-position control requires the use of a fourth terminal which is usually marked *N* for "normal" and here contact is made between *C* and *N* when the temperature is within the neutral zone.

In practically all control circuits the terminal *C* is connected permanently to the line or to the load or in case 3-wire relays are used, to one terminal of the relay coil as shown in the diagrams. Generally the control terminals are not connected to anything but switch or relay contacts within the instrument. The contacts are generally rated for not more than 250 volts and current capacity according to specifications. If there is any uncertainty about the contact capacity not more than 50 or 100 watts should be risked. When relays are used between the controller and a magnetic contactor or motor valve it is preferable to use the 3-wire type sometimes called "hold in," "mechanical latch," or "thermostat" relay, the opening of which requires that a contact be closed, for example, *C-H*. The wiring diagrams in Fig. 5 are typical and are given as an illustration, but should not be used in place of those furnished by the manufacturer excepting in the simpler cases unless such circuits are familiar.

Optical and Radiation Pyrometry

Introduction—Where a thermocouple cannot be used for the measurement of high temperatures, some form of optical or radiation pyrometer is usually employed.

The temperature of a body can be determined with precision from a measurement of the radiant energy emitted, because this energy increases at a rate many times as great as the rate at which the temperature increases. The total energy radiated increases at a rate four times that at which the temperature increases, while the spectral energy in the red portion of the spectrum increases at a rate which at 1832°F. is 18 and at 3632°F. is about 10 times the rate at which the absolute temperature increases. (The words "spectral" and "total," when applied to radiant energy, mean respectively the energy of a particular wave length and the sum of the energy of all wave lengths.) Therefore, to attain a precision of 1% in the absolute temperature, the total energy radiated need be measured only to 4%, and the spectral energy radiated need be estimated only to 10 or 20%. With practice one can estimate the brightness of a furnace to about 25% with the unaided eye.

Pyrometers in common use utilizing radiation may be divided into three classes. (1) If the indication of the instrument depends on the heating effect of all or a large part of the spectrum, it is known as a "total radiation pyrometer" or simply a "radiation pyrometer". (2) If the instrument utilizes a part of the spectrum through its effect on a photoelectric cell, it is a "photoelectric pyrometer". (3) If it measures the brightness of an object at some one wave length, it is known as an "optical pyrometer".

Fundamental Principles—The practice of optical, photoelectric, and radiation pyrometry is based upon well established physical laws which may be summarized as follows:

All bodies emit radiant energy whose amount per unit area per unit time depends upon the temperature and surface characteristics of the body. At absolute zero (-273.13°C.) no radiation takes place.

Let $E'_{\lambda\tau}$ be the spectral energy per unit wave length radiated perpendicularly by unit area of a surface at temperature T

Let $A_{\lambda\tau}$ be the ratio of absorbed to incident radiant energy (absorptive power at temperature T for wave length λ)

Let $R_{\lambda\tau}$ be the reflecting power for the same temperature and wave length. Then if the body is opaque so that the incident radiant energy is either absorbed or reflected (none transmitted)

$$A_{\lambda\tau} + R_{\lambda\tau} = 1$$

Now $E'_{\lambda\tau}$, $A_{\lambda\tau}$, and $R_{\lambda\tau}$ will depend on the character of the surface, but in accord-

ance with Kirchhoff's law, for a given value of λ and T , the ratio of $E'\lambda\tau$ to $A\lambda\tau$ is the same for all bodies (in the absence of fluorescence):

$$E'\lambda\tau = A\lambda\tau \times \text{a constant}$$

and since $A\lambda\tau$ cannot exceed unity, it is evident that a body which absorbs 100% of incident radiant energy of wave length λ will radiate the maximum energy of that wave length obtainable from any (nonfluorescent) source at the temperature in question; this energy we will call $E\lambda\tau$. Such a body is called a "black body" because we ordinarily designate the colors of bodies in terms of their appearance by reflected light. At temperatures below those at which it is self luminous, a "black body", as defined above, appears perfectly black. For example, untreated lampblack, which absorbs 95% or more of any incident wave length, radiates about 95% as much energy as a black body. The ratio of the spectral energy radiated by a body to that of the same wave length radiated by a black body at the same temperature is called the "special emissivity", often simply "emissivity", and is evidently equal to $A\lambda\tau$. The corresponding ratio for total radiant energy is called the "total emissivity".

The emissivity, both spectral and total, of lampblack is thus about 0.95 while that of a black body is unity.

The spectral emissivity of most metals in the visible spectrum (excepting that of copper, silver, and gold which is about 0.1) is around 0.3. The oxides of the metals have relatively high emissivities, from 0.5 to nearly 1.

The most perfect black body experimentally obtainable is a small opening in a hollow enclosure the walls of which are at a uniform temperature. The opening need not be particularly small relative to the area of the walls before it cannot be distinguished from a perfect black body by any measurements we can make. For example, the opening in one end of a hollow cylinder closed at the other end has an emissivity above 0.99 when the length is about 5 times the diameter even though the inner walls be of material of emissivity as low as 0.25.

Furnaces, in general, are good black bodies when the temperature inside is uniform. Placed inside such a furnace and allowed to reach equilibrium, all materials appear equally bright and seem to radiate like a black body, since what they emit, $A\lambda E\lambda\tau$, and what they reflect, $(1 - A\lambda) E\lambda\tau$, combine to equal $E\lambda\tau$, the amount that is radiated by a black body. When large errors are met with because of departures of a furnace from black body conditions, they usually arise from lack of uniformity of temperature within the furnace. Suppose a mass of cold material is to be inserted into a hot furnace. Before the mass has been heated any appreciable amount, the radiant energy coming from it will give a false indication of its temperature. If it reflects all or nearly all the light which falls on it, it will appear as bright as the furnace appeared previously, and an optical pyrometer will indicate it to be at the temperature of the furnace. On the other hand if the mass of material has emissivity of nearly 1 it will absorb all the light falling on it and consequently no light will be received from it until it has been heated to the point, about 1100°F., where it itself begins to emit light. This can be summed up by saying that an optical or radiation pyrometer calibrated to read correct when sighted upon a black body will read low when sighted upon an object whose temperature is above that of its immediate surroundings and will read high when sighted upon a body whose temperature is below that of its immediate surroundings.

Optical Pyrometry—The Wien-Planck law is the basis for optical pyrometry and states that $E\lambda\tau$, the energy of wave length λ radiated per unit wave length per unit area by a black body at absolute temperature T is a definite function of λ and T :

$$E\lambda\tau = C_1\lambda^{-5} e^{-\frac{C_2}{\lambda T}}$$

C_1 and C_2 are constants and e is the base of natural logarithms. The law is accurate to 1% for all cases where λ in microns multiplied by T in degrees C. exceeds 3000. Thus for visible light it is accurate within our errors of measurement for all temperatures below about 9000°F.

An optical pyrometer is simply a photometer using a limited range of the visible spectrum (usually red) in which the brightness of the heated body at some one wave length (the "effective wave length" of the instrument) is determined relative to that of a standard source (a black body at the melting point of gold). It usually takes the form of a telescope, which is sighted upon the body whose temperature is to be measured, with means for observing simultaneously the light from a comparison source, and for bringing about a photometric match. The comparison

source must be calibrated in terms of a black body at the freezing point of gold (defined by international agreement as $1063^{\circ}\text{C}.$) either directly or by comparison with another pyrometer which has been previously so calibrated.

In making settings with an optical pyrometer, the photometric match may be brought about either by varying the temperature of the comparison source (the filament of an electric lamp); or by varying the apparent brightness of the hot body or of the comparison source by means of various devices such as absorbing screens. To make the light approximately monochromatic there is in the eyepiece of the telescope a red glass filter which transmits only a narrow band of the visible spectrum. The value of λ to be used in the equation is the "effective" wave length of the light transmitted by the filter glass.

Types of Optical Pyrometer—There are two general classes of optical pyrometers, as follows:

(a) *Variable Intensity Comparison Lamp Type*—This type includes those in which the brightness of the comparison light (an electric lamp) can be varied so as to match the apparent brightness of the light from the body under test, the brightness of the comparison lamp being at all times definitely related to the current which passes through it. This class of instrument is the one which is used in the realization of the International Temperature Scale above the gold point. It requires a precise means of controlling and measuring the filament current, the filament resistance, or the drop of potential through the filament.

(b) *Constant Intensity Comparison Lamp Type*—This type includes those pyrometers in which the comparison lamp filament is maintained at a constant brightness and the brightness of the light from the hot body is cut down to match it by means of an absorbing device such as a glass wedge or a polarizing prism interposed between the hot body and the comparison source. Usually an electric lamp is employed for the comparison source and requires means of standardizing the filament current at only one value, so that the use of a long scale ammeter is unnecessary, resulting in a more compact and lighter instrument. The disadvantages are: (1) That all brightness matches must be made at the relatively low intensity corresponding to the lowest temperature to be measured with the instrument; and (2) the reading involves holding the lamp current at the standard value as well as manipulating the absorbing device.

(a) *Description of Variable Intensity Comparison Lamp Type*—One type of optical pyrometer is shown in Fig. 6. The objective lens, L , is focused so as to form an image of the object, the temperature of which is being measured in the plane

Fig. 6—Disappearing filament, variable current optical pyrometer.

of the filament of a small tungsten filament lamp F . The eyepiece is focused upon the filament and the image, both being simultaneously in focus since they are in the same plane. A red glass filter is mounted in the eyepiece to transmit approximately monochromatic light to the eye. In making an observation, the current through the lamp is adjusted by the rheostat until the tip or some other predetermined part of the filament is of the same apparent brightness as the source viewed. When this condition is reached, the comparison portion of the filament is indistinguishable from the portion of the image of the hot body which it crosses. If the current is too large, it appears as a bright line, and if too small, as a dark line, across the image. The value of the current in the lamp at disappearance of filament is read by means of a milliammeter, and the corresponding temperature is read from a table. In order to avoid deterioration of the filament and blackening of the bulb, the lamp should not be operated at temperatures above $2700^{\circ}\text{F}.$ For higher temperature readings, standardized absorption glasses are placed between the lamp and the objective, so as to diminish the intensity of the light from the object under observation.

A check of an instrument of this type should also include a check of the milliammeter calibration. This is at least as important as that of the lamp.

(b) *Description of Constant Intensity Comparison Lamp Type*—The principle of one of these pyrometers is shown in Fig. 7. It consists of a telescope with an objective lens, A, and an eyepiece, D, an electric lamp, C, and a glass wedge, B. The filament of the lamp is mounted at the focal point of the objective lens and a small section of the filament is viewed through the eyepiece. The observer sees this small section of the filament superimposed on the image of the source sighted upon.

The filament operates at a definite brightness obtained by setting the current through the lamp to a standard value by means of a rheostat and milliammeter. A semicircular wedge of black absorbing glass, which can be rotated through any desired angle, is mounted at B. By varying the angular position of this wedge a

Fig. 7—Disappearing filament, optical wedge type optical pyrometer.

thicker or thinner portion is brought into the line of sight and the brightness of the image of the source viewed may be matched with the brightness of the section of the filament. A scale attached to the wedge is calibrated directly in degrees F. for both high and low range. The high range is secured by interposing a second, fixed, absorbing glass in the line of sight. A red filter glass is used in the eyepiece.

Range and Accuracy of Optical Pyrometer—The useful range of the optical pyrometer begins at about 1200–1500°F., since the radiation emitted by bodies at temperatures less than this is of low luminosity, and balances are difficult even in a darkened room. No upper limit can be set to the temperatures which can be read by means of an optical pyrometer.

The National Bureau of Standards will certify the readings of a commercial type of disappearing filament variable current optical pyrometer to $\pm 9^\circ\text{F.}$ up to 2550°F.; $\pm 18^\circ\text{F.}$ from 2550–3300°F.; and $\pm 36^\circ\text{F.}$ from 3300–5150°F. Readings with the same instrument under practical shop conditions can be repeated by a practiced operator to about one third the limits given above. It does not necessarily follow that all types of optical pyrometers can be operated within the same limits of error.

Precautions for Optical Pyrometer—In adopting the optical pyrometer for a particular use, the limitations imposed by the laws of radiation must be carefully considered. Under some conditions, the radiation emitted from a furnace or from an object within it is so nearly that of a black body that true temperatures are given by a measurement of its brightness. If, however, the temperature of the furnace walls differs considerably from that of an object within the furnace upon which the pyrometer is sighted, or if flames are present, or if bright daylight or artificial light may enter the furnace to be reflected back to the pyrometer, a considerable error may result. One method of reducing stray reflections in a heat treating furnace is to sight into a deep cavity in the metal being heated. Temperatures of closed furnaces can be read by the use of a refractory tube, closed at one end, and so placed that the pyrometer can be sighted through the open end upon the closed end, which is inserted in the furnace. The tube must be thoroughly burned out to remove any tendency to produce smoke before it can be used in making temperature readings.

Care should be taken not to sight through smoke or visible fumes. A considerable depth of clear, nonluminous flame may be sighted through without introducing an important error, but it is safer to turn off the flame while reading, or to sight under it.

When taking temperatures of bodies outside a furnace, black body conditions will not, in general, exist, unless a closed end tube or its equivalent, such as a deep cavity in the body, is used. The radiation from surfaces of carbon and of a few oxides, in the solid condition, such as that of iron, approximate closely to that from a black body so that the optical pyrometer gives temperatures which are accurate for practical purposes on such surfaces in the open. The temperature of steel billets, or sheet, if free from loose scale can be measured successfully in the open with the optical pyrometer.

The emissivity of molten metal surfaces free from oxide is low, and there is a characteristic emissivity for each material, which must be known and the corresponding correction applied to the apparent or brightness temperature to get true temperature. When it is merely desired to repeat conditions on a given material,

and there are no complicating factors such as the changeable film on cast iron (Table II), apparent temperature will serve as well as true temperature and the emissivity correction need not be known. Since liquid metal surfaces are good reflectors, readings should be made from such a position that reflections from flames, lights, or windows do not enter the pyrometer. Table II gives the corrections in °F. to be applied to readings made with an optical pyrometer employing a red filter glass transmitting a mean wave length of 0.65μ .

A tapping or pouring stream of steel usually shows a set of bright streaks on a darker background. The dark surface is the flat or convex clean metal to which the emissivity of 0.40, on which the corrections in column 3 of Table II are based, is applicable. It is suspected that certain alloying elements, such as manganese, increase the emissivity above 0.40 and consequently lead to high readings of the temperature.

Size of Object—In order to determine the disappearance of the filament sharply it has been found that the image of the hot body as seen in the telescope should be at least four times as wide as the image of the filament. In practice, using generally available instruments, the smallest object that can be sighted on with convenience and certainty must have a dia. of not less than 0.1 in. In principle, however, there is no objection to measuring the temperature of far smaller objects by the comparison of brightness.

If it is desired to measure the temperature of a furnace in which black body conditions are approximated, the pyrometer may be sighted on an opening in the furnace from a position such that it receives direct radiation from the interior of the furnace.

Calibration and Checking of Optical Pyrometer—The optical pyrometer is sent out by the maker with a calibration which should remain good over a period of years if the instrument is carefully used. But changes in calibration may occur, due to deterioration of the lamp filament, clouding of the bulb, pitting or scratching of the objective lens, or changes in the transmission of the absorbing screens if materials other than glass are used. To guard against such changes the instrument should be frequently checked.

At temperatures below 2750°F. checking and calibrating can be accomplished by direct comparison of the optical pyrometer reading with the simultaneous reading of the emf. of a standard thermocouple taken with a potentiometer. If points above this temperature are to be checked, the comparison should be made with the reading of a standard optical pyrometer in the manner described later.

To carry out the former method, the thermocouple is heated in a closed furnace which is free of smoke and incandescent flame, and at such a point in the furnace that the portion of the thermocouple protecting tube immediately surrounding the measuring junction of the thermocouple would be visible through a peep hole if the temperature were nonuniform enough to make it visible. If the work is done in the laboratory, a tubular type electric furnace, not less than 24 in. long and 1.5 in. or less in dia. should be used. The standard thermocouple in this case is inserted at one end of the furnace to such a depth as will bring the end of the thermocouple tube to the middle of the furnace, the other end of the furnace being left open so that the end of the thermocouple tube is in sight.

After bringing the furnace up to the desired temperature, it should be held as nearly constant as possible, and, with the optical pyrometer sighted on the end of the thermocouple tube, readings should be taken on each as nearly simultaneously as possible. Repeat readings until a definite relationship between optical pyrometer and thermocouple readings is established. When, as is usual, a range shifting device is a part of the optical pyrometer, there will, in general, be a considerable overlap between the ranges. In such a case it is well to check at a point lying within the overlap, so that the reading may be applied to each scale, and a check secured upon the accuracy of the range shifting medium.

For checking at points beyond the range of a platinum-platinum-rhodium thermocouple, the same procedure, as outlined above, may be followed, substituting a standard optical pyrometer and a fire clay target for the thermocouple. The fire clay target is mounted in the furnace in place of the thermocouple and the standard and unknown pyrometers alternately sighted into the same end of the furnace.

A more convenient means of checking optical pyrometers up to about 3450°F. is by the use of a ribbon filament tungsten lamp. The filament should be at least $\frac{1}{4}$ in. wide and long enough to ensure a uniform temperature over its central portion. A shallow notch in the filament midway of its length may be used to mark the point on which the pyrometer is to be focused. With a standard optical pyrometer focused on the flat filament the current through the latter is adjusted to produce the desired temperature in the flat filament, as read by the optical pyrometer. The pyrometer to be checked is now substituted for the standard instrument and a reading made with it while the current in the flat filament is held constant. While the tungsten filament is not a black body, if the two optical pyrometers compared are of the same type, employing the same band of the spectrum in each, the readings of both will depart from the true temperature of the filament by the same amount. The standard pyrometer having been originally calibrated to read in terms of black body temperature, the pyrometer being checked will be calibrated in the same terms.

It will be noted that the methods of check just described require the use of an optical pyrometer which is maintained as a standard and used only for checking purposes, and which may be identical in structure with the working pyrometers. Where no pyrometer is available for use as a standard, a reasonably accurate check may be obtained by the use of the flat filament lamp alone, if the current values corresponding to certain fixed temperatures have once been determined, either by the user or by a testing laboratory. The flat filament lamp can then be maintained as a standard source of temperature.

Advantages and Disadvantages of the Optical Pyrometer—Some of the advantages of the optical pyrometer have been brought out in the preceding discussion. These include its utility for measuring high temperatures, and measurements, also at lower temperatures, on inaccessible bodies, moving bodies, small bodies whose temperature would be affected by the attachment of a thermocouple, and for occasional readings when the installation of a thermocouple would not be economical or feasible. Other advantages are that no part of the instrument is exposed to destructive heating effects, and that the indicated temperature is related directly to the temperature of the heated body under test and not to the temperature of some adjacent body (for example a thermocouple), which is assumed to be at the same temperature as the heated body under test.

The principal disadvantages are the ease with which errors may be introduced by absorbing screens of smoke or incandescent gases between the observer and the object under test, and the fact that with most instruments each reading is the result of a photometric match made by an individual observer, and affording an opportunity for dishonest or prejudiced readings, as well as accidental errors.

Errors introduced by uncertainty as to departure from black body conditions have been pointed out in the discussion of the instrument.

Radiation Pyrometers—The Stefan-Boltzmann law states that the total radiation from a black body is proportional to the fourth power of its absolute temperature, or since it is receiving radiation from its surroundings while emitting, its net loss of energy per unit area per unit time is proportional to the difference between the fourth power of its absolute temperature and the fourth power of the temperature of its surroundings. This law is the basis of total radiation pyrometry, and is expressed as follows:

$$E = K (T^4 - T_0^4)$$

where E is the net energy lost by radiation per unit area per unit time; T is the absolute temperature of the black body; T_0 is the absolute temperature of the surroundings; and K is a constant of proportionality.

It is essential in the use of radiation pyrometers to collect the energy emitted from an area of the hot body which subtends a definite solid angle at the instrument, absorb this collected energy in a receiver, and measure the heating effect thus produced in the receiver. The receiver is commonly a blackened disk, on which there is formed an image of the source or of some intermediate opening, and to which are attached the measuring junctions of one or more thermocouples. The cold junctions of these thermocouples are in the same enclosure with the disk, but not exposed to the focused radiation. When radiant energy is received from the source, the disk and its attached thermocouples are heated, their temperature rising until a state of equilibrium is reached, when heat is lost by radiation, conduction, and convection to nearby parts of the instrument at exactly the same rate as it is received by radiation from the source. A temperature differential is thus established between the hot and cold junctions of the thermocouples, the magnitude of the difference being dependent on the rate at which radiant energy is sent out from the source. The rate at which radiant energy is emitted from the source is a function of its temperature. Hence, the emf. developed by the thermocouples in the pyrometer is definitely related to the temperature of the source. The junctions, however, are not heated to the temperature of the source, but to some much lower temperature, usually not exceeding 212°F., even when measuring the temperature of a source heated to 3600°F. or higher. No attempt is made to maintain the cold junctions of the thermocouples at a constant temperature, since the difference of temperature between hot and cold junctions for a given temperature of the source is practically independent of the temperature of the enclosure in which they are placed, over the range of surrounding temperatures to which the instrument may be subjected or about 32-140°F. If the thermocouple materials are so chosen that their emf. is practically constant for a given temperature difference, whether the cold junction is at 32 or at 140°F. or any intermediate temperature, the calibration will be nearly independent of surrounding temperature. This condition is met if the thermocouple materials are chosen from some of the metals commonly employed in thermoelectric pyrometry, such as copper, iron, constantan, Chromel, and Alumel. If one of the materials is an alloy chosen for its high thermal emf. at low temperatures against the other material, without reference to the uniformity of this emf. over the range of surrounding temperature to be encountered, considerable change of calibration with change of surrounding temperature is likely to result.

The sensitive element is the heart of the radiation pyrometer, and many, if not most of the troubles which have been encountered in the practical use of these instruments for temperature measurements may be traced to the thermocouple materials, which have been chosen for their high thermoelectric power, rather than for stability, strength, and freedom from variation with surrounding temperature.

The emf. developed by the thermocouple may be measured by means of a millivoltmeter, or preferably a potentiometer, and the scale of the measuring instrument may be calibrated to read directly in temperature of the source. The scale will not be uniform, since the emf. developed is approximately proportional to the fourth power of the absolute temperature of the source. The measuring instrument may be either an indicator, a recorder, or a controller, or any combination of the three.

Types of Radiation Pyrometers—Commercial radiation pyrometers do not follow the Stefan-Boltzmann law exactly, primarily because not all the wave lengths radiated by the source reach the sensitive element. Part of this energy is generally absorbed by windows, lenses, or mirrors, and not all the radiation reaching the hot junction is absorbed by it, since it is not perfectly black. A secondary reason for

departure from the law is that the emf. response curve of most thermocouples is not a straight line, and the emf. generated is therefore not exactly proportional to the difference in temperature at the hot and cold junctions. Consequently, the term, "total radiation pyrometer", can be used only by courtesy, even in the most favorable case, which is that of an instrument without windows, using a mirror for concentrating the radiation on the thermocouple; hence, the use of the term "radiation pyrometer" is to be preferred, as has been the practice in this article.

Radiation pyrometers may be classed in two ways according to their optical systems: (a) As mirror type or lens type, depending upon the focusing agent; and

(b) as fixed focus or variable focus, depending upon whether means are provided for changing the distance of the thermocouple from the focusing agent to accommodate changes in distance of the object. Classification (a) is the more important. Fig. 8 and 9 represent typical forms of mirror and lens type instruments.

In Fig. 8 the diaphragm opening B and thermocouple b are located at conjugate foci of the spherical mirror DD'. The diaphragm opening acts as a secondary source. Readings are theoretically independent of distance from the source provided that the source is large enough to cover completely the base of a cone determined by the formula:

$$\text{Minimum diameter of source} = \frac{MD}{N}$$

where M = distance from point C to source; N = distance from point C to aperture B; and D = diameter of aperture B. This is a fixed focus instrument.

Fig. 9—Variable focus lens type radiation pyrometer.

Fig. 9 shows a typical lens system. The lens L focuses radiant energy from the object O upon the diaphragm D₂ behind which is the thermocouple disk b. D₁ is a limiting diaphragm, which fixes the solid angle of the rays incident on D₂. E is an eyepiece, used in pointing the instrument on the desired portion of the object O. Theoretically the distance between L and b must be changed whenever the distance of the instrument from the object is changed, and it is therefore a variable focus instrument. Practically, beyond a certain distance which is roughly 10 times the focal length of L, the focus is independent of distance, and for such distances it may be treated as a fixed focus instrument. The minimum diameter of the source is fixed by the condition that its image must be at least large enough to fill the aperture D₁.

$$\text{Minimum diameter of source} = \frac{MD}{N}$$

where M = distance from L to source; N = distance from L to D₁; and D = diameter of aperture D₁.

The methods of focusing employed in these two types of instruments have each their advantages and disadvantages. The mirror type instrument can be made to follow the Stefan-Boltzmann law more closely than the lens type, since the selective absorption of the mirror is much less than that of the lens, even when the latter is made of fused quartz, since glass and fused quartz are opaque to much of the long wave length radiation which predominates in the spectrum emitted

by bodies in the usual range of temperature measurements. It can therefore be employed for measuring lower temperatures than the lens type. A further advantage is that the mirror focuses all wave lengths at the same distance, while, due to the dispersion of the lens material, the lens focuses the long wave lengths at a greater distance than the short ones, so that it is impossible to have all parts of the spectrum in sharp focus. In most mirror type instruments the first advantage is sacrificed to a considerable extent by introducing a window between the diaphragm opening B and the thermocouple b (Fig. 8) in order to keep dust, fumes, and moisture from reaching the mirror and the thermocouple, the window being located where it is readily accessible for cleaning.

The lens type instrument has the advantage of not requiring as large a field of view at a given distance. In Fig. 8 it is seen that the mirror type instrument requires a field which covers the base of a cone with its apex at C and limited by the aperture B, while the lens takes in a cone of rays from each point on O, to be focused on D, and if the distance of O from L is such that O need be no larger in diameter than L to form an image filling the aperture in D, a cylindrical surface with the diameter of L extending from L to O will not interfere in any way with the radiation received by D, and b. Hence, the lens type instrument is particularly adapted for use with closed end tubes, of moderate diameter, where the mirror type instrument as shown could not be used. This advantage is obtained at the expense of some loss of sensitivity. It also has the advantage of smaller size, making it adaptable for mounting in positions where space is not available for the mirror type of instrument.

The Stefan-Boltzmann law does not apply to the selected radiation employed by the lens type instrument nor to the mirror type using a protective window. When used to measure the temperature of nonblack bodies, corrections must be applied as in the case of all radiation pyrometers, and in making these corrections it must be borne in mind that these corrections are usually four or five times as large as corrections for optical pyrometers and somewhat smaller than those given for *total* radiation pyrometers. The departure of the correction from the values given for total radiation pyrometers will vary with the material and thickness of the lens or window employed in the particular make of instrument.

Installation—The radiation pyrometer receiving tube should be located where the surrounding temperature does not exceed the maximum allowable value as recommended by the manufacturer. In many cases it is necessary to resort to water or air cooling. Too high a temperature may ruin the sensitive element or damage other parts of the instrument. It is particularly important that limiting diaphragms do not become overheated, as these may radiate to the thermocouple sufficiently to increase the readings considerably.

Proper distance from the source depends upon the size of the source, and upon the type of radiation pyrometer employed. Most manufacturers state the least allowable ratio of source diameter to distance from source. When openings cannot be left in furnace walls, a closed end tube may be inserted with the closed end extending into the region where the temperature is to be measured. The radiation pyrometer is then sighted upon the closed end of the tube. It is important that the tubes used do not give off smoke or such gases as carbon monoxide and carbon dioxide, which absorb radiant heat.

Consideration must also be given to the possibility of mechanical injury to the equipment. If a safe location cannot be found, it is necessary to provide a structure for protecting the tube. Often the water jacket may serve for both cooling and for mechanical protection. In any case the protecting structure must be large enough to provide sufficient cooling area.

Range—Theoretically, radiation pyrometers may be used throughout the entire temperature range. In commercial practice they are available for the measurement of surface temperatures as low as 300°F., and no definite limit can be set to the high end of their range.

Accuracy—Owing to the relatively large source of uniform temperature required, it is more difficult to calibrate a radiation pyrometer than either a thermocouple or an optical pyrometer. Therefore, the accuracy of calibration of the radiation pyrometer, in general, may be expected to be somewhat lower, the amount depending upon the care which has been taken in the calibrating process. In the field, additional errors may enter in various ways, as a result of working conditions differing from those which existed at the time of calibration. Such errors may result from the following causes:

- a. Deviation from black body conditions, the exact corrections for which are unknown, for example, lack of uniformity of temperature within furnaces and interreflection due to irregularity of surface or concave surfaces of bodies in the open.
- b. Parasitic temperature effects at the thermocouple due to nonuniform heating of the housing.
- c. Abnormal radiation from the limiting diaphragm due to overheating.
- d. Dust, stains, or condensed moisture on mirrors, lenses, or windows.
- e. Absorption of radiation by carbon dioxide, carbon monoxide, and water vapor in the line of sight (reduced by use of windows or lenses of glass or fused quartz in the instrument).
- f. Variation of reading with distance from source and with size of source.

It will be evident from a consideration of the above list of possible errors that the accuracy to be expected depends to a great extent upon the nature of the process and the care taken in the installation and maintenance of the equipment. Under favorable conditions, such as a fixed installation reading a constant temperature, an accuracy of 25°F. is obtainable in the range from 1000-3000°F.

Table III gives the corrections in °F. to be applied to readings made with a total radiation pyrometer. These corrections are only approximate and in view of the fact that no existing pyrometer is, strictly speaking, a total radiation pyrometer, they do not apply exactly to any particular instrument. The table serves to point out orders of magnitude of the corrections to be applied. In general, it is preferable

Table III
Total Radiation Pyrometer Emissivity Corrections

to determine the corrections to be applied on a given type of work by making simultaneous readings on the surface in question with optical and radiation pyrometers, and determining the true temperature by applying the correction from Table II to the optical pyrometer reading, since the optical pyrometer corrections are much more reliable than those given in Table III for radiation pyrometers.

Photoelectric Pyrometers—Another type of pyrometer, intermediate in character between the optical and the total radiation, is the photoelectric. It does not measure brightness, as does the optical pyrometer, but it takes only a limited portion of the radiant energy from the hot source and converts it by various devices into the energy of an electric current, which can be measured by well known means.

The simplest type of photoelectric pyrometer utilizes the self generative type of photoelectric cell, such as the Photronic cell, in which the radiant energy is converted directly into an electric current by a sensitized surface. These cells are sensitive to the visible spectrum. The current can be sent through a resistance and the emf. drop across the resistance can be measured by a potentiometric indicator or recorder such as those described under "Thermoelectric Pyrometry." Or the current can be amplified, as by an amplifier of potentiometric type, and thus used to operate directly a current recorder.

If the vacuum or gas filled types of photoelectric cell are used, the energy comes mainly from a battery that applies a voltage to the terminals of the cell and thus sets into directed motion the electrons set free by the radiant energy. These cells are influenced by the infra red as well as by the visible spectrum.

A type of photoelectric pyrometer that utilizes the comparison principle with a standard lamp is illustrated in Fig. 10. Two photoelectric cells, P_1 and P_2 , are used to compare the light intensity of the lamp filament F and the heated object O , and an amplifier

Fig. 10—Comparison type of photoelectric pyrometer.

under control of the photoelectric cells automatically keeps the current through the lamp filament F at the proper value to make the intensity match the illumination from the furnace that reaches P_1 through objective lens L . Temperatures are read from a continuously recording current meter M .

Precautions—The remarks in the paragraph on accuracy will serve to indicate some of the precautions to be observed with all radiation and photoelectric pyrometers. All that has been said under "Precautions" in connection with the optical pyrometer concerning emissivity applies with even greater force here. The difference between the true and the apparent temperature as indicated by a radiation pyrometer calibrated for black body conditions amounts to over 100°F ., when the hot body is of iron, with an oxidized surface, such as a billet, at a temperature of 1700°F .

The size of the object to be sighted on is of much more importance in using the radiation and photoelectric pyrometer than with the optical pyrometer. It is essential that the object shall completely fill the field of view of the sensitive element. The conditions to be satisfied have been discussed under "Types of Radiation Pyrometers."

Calibrating and Checking—In order to carry out a preliminary calibration of a radiation pyrometer a good black body furnace must be available. This may take the form of a graphite tube, electrically heated, and provided with suitably spaced and dimensioned graphite or refractory diaphragms to restrict the loss of heat by radiation to that which enters the pyrometer.

A surface forming a diaphragm across the tube serves as the source on which the pyrometer is focused. The temperature of the source may be determined either by means of a standard platinum-platinum-rhodium thermocouple or an optical pyrometer. A deep closed-end tube of refractory material, of such internal diameter that its closed end completely fills the field of a radiation pyrometer sighted into its open end and heated over a length at least four times its internal diameter, forms a close approach to a black body source. It may be heated in an electric or a gas fired furnace. In this case, the calibration is most conveniently made against an optical pyrometer.

A secondary calibration may be made, in which comparison is made with a similar pyrometer, the calibration of which is known. Comparison is made by exposing the standard and the instrument under test to the same area of the hot body, either alternatively or simultaneously. A source which has been found useful for this type of test is an electrically heated nickel sheet, approximately 6 in. square, and 0.01 in. thick. This is suitable for use up to about 2400°F . In use a tough coating of nickel oxide forms, which does not scale if the cooling from 900°F . to room temperature takes place slowly.

When the radiation pyrometer is used for control purposes only, it may be unnecessary to know the true temperature. Here the optical pyrometer will serve to determine if the radiation pyrometer is retaining its calibration. It is merely necessary to take an occasional reading with the optical pyrometer and note if the radiation pyrometer bears the same relation as before to the observed optical pyrometer reading. Since the radiation pyrometer may give appreciably different results with large sources than small ones, even when the theoretical requirements are fulfilled, and may also show some variation with distance from the source, these quantities should be fixed when possible.

The time lag may vary from the practically instantaneous response of the photoelectric pyrometer, where the speed is limited only by the indicating mechanism and the time of response of the comparison lamp filament to changes of current in it, to a matter of minutes in some types of radiation pyrometer. The more commonly used thermoelectric radiation pyrometers will give a steady reading in from 1-10 seconds after exposure to the source of radiation.

Advantages and Disadvantages—Comparison with the Thermocouple—In the part of its range common to that of the thermocouple, the radiation pyrometer has the following relative advantages:

- a. No contact with the hot body is required, making it possible to measure the temperatures of moving objects, such as billets and strip in the steel mill and rotary kilns in the cement plant.
- b. The time lag is generally much less than that of a thermocouple particularly when the latter must be protected by a heavy ceramic or metal tube.
- c. The instrument is not subject to deterioration through exposure to the high temperature being measured or through contamination by furnace gases.

Disadvantages are:

- a. Relatively large sources are required.
- b. Corrections must be applied to the usual "black body" calibration when black body conditions do not exist in practice.
- c. The accuracy obtainable is generally less.
- d. The first cost is higher.

Comparison with the Optical Pyrometer—Advantages relative to optical pyrometers are:

- a. The personal element does not enter into the measurement.
- b. Direct reading indicators, recorders, and controllers are available.
- c. Lower temperatures can be measured.

The disadvantages are:

- a. Larger sources are necessary.
- b. Corrections for deviations from "black body" conditions are larger and less accurately known.
- c. In general the accuracy is lower.

Lead Baths

By R. B. Schenck*

The various liquid heating mediums employed in the treatment of steel fall into three general classes: Metals, salts, and oils. Of all the metals, lead is the only one which can be considered as a commercial bath material.

Properties of Lead

Melting point, °F.....	621
Heat to raise metal from 60°F. to melting point, B.t.u.....	18
Latent heat of fusion, B.t.u.....	10
Mean specific heat, liquid state.....	0.034
Boiling point, °F.....	2775
Unit weight, solid, lb. per cu.in.....	0.41
Unit weight, liquid, lb. per cu.in.....	0.37

Fig. 1 gives the heat content curve of lead for temperatures between 60 and 1700°F.

Comparative Properties of Lead and Salts

General Comparison—In comparing the properties of lead with those of the commercial salt bath materials, there are certain marked characteristics which differentiate the two classes. Lead is higher in specific gravity, higher in thermal conductivity, lower in specific heat and lower in latent heat of fusion. The melting point of lead is lower than that of any of the salts used for hardening, but higher than most of the tempering salts. Lead has a total working temperature range of about 650-1700°F. The salts, as a class, have a range of approximately 350-2350°F. Lead oxidizes readily, but is otherwise stable, and has no appreciable chemical action on the metals with which it comes in contact. Many of the salts tend to decompose, and some have various chemical effects on the metals. Lead does not adhere to the stock unless impure or oxidized, while the salts cover the work with a film of bath material. Lead is not hygroscopic, whereas the salts all possess this property to a greater or lesser degree. Lead has a much higher heating rate.

Specific Gravity—Steel sinks in all of the salts, but floats on lead unless immersed by suitable fixtures. Lead is higher in first cost on the volume basis, but its lower consumption generally results in lower ultimate cost. The specific gravity of molten lead is approximately 10, while that of the salts is about 2.

Thermal Conductivity—The high thermal conductivity of lead is one of its most valuable properties, tending toward rapid heating, high output, uniform temperature throughout the bath, and high thermal efficiency.

Specific Heat—Because of its low specific heat, the thermal capacity of lead is less than that of most of the salts, even on the basis of volume. This difference, however, is not sufficient to be much of a factor in commercial operation. Low thermal capacity results in greater temperature drops where cold work is introduced and decreases thermal stability. It also tends to reduce time and fuel in bringing a cold pot up to heat; it probably increases thermal efficiency in batch operation, and maintains a greater average temperature differential between the pot and the source of heat.

Latent Heat of Fusion—The low latent heat of fusion of lead tends to cause the formation of heavier layers of solidified bath material when cold stock is placed in the pot. The fact that, independent of melting point and other considerations, these layers actually form more extensively in all salt baths is due to the much lower thermal conductivity of the salts. On the basis of volume, the number of heat units involved is less for lead than for most of the salts, with the result that less time and fuel are required in bringing a cold pot up to temperature.

Melting Point—The melting point of a bath material not only determines the minimum temperature of operation, but also has a pronounced effect upon the heating rate when charging cold stock. The solidified layer of bath material, which forms on cold stock in lead and salt baths, must be completely melted before the temperature of the stock can rise above the melting point of the bath. The lower the melting point, the less will be the weight of frozen material formed. The greater

*Metallurgical Engineer, Buick Motor Co., Flint, Mich.

the difference between the melting point and the bath temperature, the more rapidly will this layer be removed. Heat conductivity plays an important part in this connection, with the result that, for the same temperature differential, the frozen layer melts much more rapidly in lead than in salt baths. Lead can, therefore, be satisfactorily used at temperatures closer to the melting point, and is less adversely affected in heating rate at higher temperatures. Other things being equal, a bath operating at 1500°F. with a melting point of 700°F. will heat more rapidly than one operating at the same temperature with a melting point of 1300°F. In some cases, where intricate parts would otherwise be inclined to warp or crack in hardening, the retardation of heating due to the solidified layer is distinctly advantageous. Preheating to temperatures below the melting point will decrease the amount of frozen material, and temperatures above the melting point, will, of course, eliminate it completely.

Temperature Range—The wide temperature range of lead, approximately 650-1700°F., makes the lead bath available for the majority of hardening and tempering operations. The lower limit is dependent primarily upon the melting point, while the upper limit is determined by the ability of the pots to stand up and the coverings to give adequate protection against oxidation.

Some of the salt mixtures are used as high as 2350°F. for the hardening of high speed steel, and others are employed for tempering as low as 350°F. All intermediate ranges can be covered by selection of the proper salt mixtures.

Oxidation and Decomposition—Lead is readily oxidized by the air at all temperatures when molten and must be protected by a suitable covering to prevent excessive formation of dross. Lead oxide is sufficiently insoluble in molten lead to preclude any appreciable contamination of the bath as a whole. Aside from this tendency to oxidize, lead is inherently stable in compositions when used as a bath material.

Some of the salts tend to oxidize or decompose on continued use, forming gaseous or infusible products, accompanied by a change in composition of the whole bath. The mixtures containing cyanide oxidize quite rapidly, CN being replaced by CO. Many of the chlorides and carbonate mixtures tend to form sludges which collect in the bottom of the pot and interfere with heat transfer. Additions of cyanides will usually correct this trouble, but cyanide salts are costly and the tendency to form a "case" on the work is sometimes objectionable.

Pitting and Decarburization—Lead baths, under conditions of normal operation, seem to be entirely free from any tendency to pit or decarburize, but many of the salts used in the hardening range are very troublesome in this respect and require special treatment when used on finished parts. Repeated heating and cooling over a wide range of temperature, or desulphurization with cast iron chips, is often necessary to prevent pitting. The frequent addition of "rectifiers," such as sodium cyanide, borax, or boric acid, will eliminate decarburization.

Fig. 1—Heat content for lead

Rusting of the Stock—Lead does not leave any corrosive agent on the stock after heat treatment. Certain salts, especially the chlorides, rust steel very readily in the presence of moisture, so that cleaning with hot water or hot sal soda solution is frequently necessary to remove the last traces of salt.

Chemical Action on Pots—Lead seems to have no appreciable chemical action on the pot materials, but some of the salts are troublesome in this connection. The nitrates and nitrites attack metals violently when slightly overheated and the cyanides are very detrimental to chromium-nickel alloy pots if permitted to enter the combustion chamber. Most of the other commercial salt mixtures have little action on the pots, and the shorter life frequently obtained in comparison with

lead is probably due more to local overheating than to any other cause. Local overheating is much more prevalent with salts, because of their lower heat conductivity. Sludge formation may also be a contributing factor of considerable importance.

Adherence to the Stock—The tendency of lead to oxidize is a troublesome feature, resulting in loss of lead and dirty stock. Suitable coverings must be used, but at low temperatures even the best coverings may be inadequate and special means are often required to clean the work. Above 850°F., however, lead can be well protected and the bad effects of oxidation kept to a minimum. Under proper conditions the steel comes out remarkably clean.

Salts cover the stock with a continuous film of the bath material, resulting in large mechanical losses, but because of the solubility of these materials in water, the work is easily cleaned. The adhering film of salt may be an advantage where it is important to have a fine finish, as this film effectively prevents oxidation by the air upon removal from the bath. The thickness of the film, and, consequently, the mechanical loss, is largely dependent upon the fluidity of the bath.

Affinity for Water—The fact that lead does not absorb water is a decided advantage. Some of the salts are objectionable in this respect, and require careful handling in order to avoid dangerous explosions when they are added to a molten bath. All the salt bath materials have more or less affinity for water and should be shipped and stored in air-tight containers.

Heating Rate—The heating rate, or time required to bring a piece of steel of a given size up to the temperature of the bath, is mainly dependent upon heat conductivity and melting point. Lead so greatly excels in heat conductivity that, for any temperature within its range of operation, very few of the other bath materials approach it in rate of heating.

Fig. 2 shows the comparative heating rates of steel in a lead bath, a cyanide bath and an oven furnace. The test piece consisted of a cylinder of low carbon steel with a stem on one end bored to admit a thermocouple. All of the units tested were of sufficient size to prevent more than slight temperature drops when the cold test piece was introduced. The lead and cyanide baths were of exactly the same size. The baths and furnace were stationary in temperature and remained practically so without firing, throughout the duration of the test. The cyanide mixture showed by analysis, at the time the test was performed, a composition of approximately 14% NaCN, 14% NaCl, and 72% Na₂CO₃. The extremely rapid rate obtained in lead is clearly shown. It is also interesting to note that lead heats to the required

Fig. 2—Comparative heating rates of steel in a lead bath, a cyanide bath, and an oven furnace.

temperature in the same time at 900 and 1500°F., while the oven furnace takes longer to heat to the lower temperature.

Quality of Lead Used—The grade of lead purchased for baths is not of great importance. Ordinary pig lead seems to answer every requirement. Special grades, claimed to be superior for lead pot work and marketed at a higher price, apparently give no better results than the regular commercial pig. Tin, even in small percentages, tends to cause lead to stick to the work and is to be avoided. Tin contamination is sometimes encountered in lead which has been refined from

cross. Sulphur is also claimed to be an objectionable impurity.

Pot Materials—There are, in general, three classes of pot materials: Cast iron, steel, and the special alloys.

Cast Iron—Cast iron pots, if properly made, usually give good service at temperatures below 1300°F. At higher temperatures, cast iron has not been found satisfactory, except in small units operated at low output. Its composition ranges from ordinary gray iron to the so-called alloy iron, made with additions of steel scrap and containing small quantities of alloying elements.

Steel (Cast and Pressed)—Cast steel is used for all temperatures throughout the range of lead. Below 1300°F. it gives excellent results. At higher temperatures its life depends largely on the conditions of service. The chemical composi-

tion varies considerably, and within certain limits is of much less importance than freedom from porosity. Many different compositions give equally good service if the castings are sound.

Pressed steel pots are also successfully used throughout the temperature range of lead. Their advantage lies in light weight and freedom from porosity. Unfortunately they do not possess the flexibility of design attainable with cast steel, and on account of die cost are, for the most part confined to standardized shapes and sizes.

Special Alloys—Most of the special alloys come under three general classifications: High nickel-chromium, low nickel-chromium, and chromium. The alloys of the first class contain in percentage about 65 Ni and 15 Cr; the second class 35 Ni and 15 Cr; and the third class 25 Cr. These materials are all much higher in price than steel, and to prove economical must give correspondingly longer service. They are always used at temperatures over 1300°F., as they cannot compete with cast iron and steel in the tempering range.

Special alloy pots are usually cast, although certain compositions are obtainable in pressed form. As in the case of cast steel, the composition of a cast alloy pot is often of less importance than its freedom from porosity. The advantages and the limitations of design of the pressed steel pot apply in even a greater degree to the pressed alloy pot.

Pot Design—An important factor in obtaining efficient service is the design of the pots. Sharp corners and abrupt changes of section should be avoided wherever possible. Large radii in corners below the lead level are especially important.

Thickness of section is a much disputed point. The cast special alloys, as a rule, do not require as heavy bottoms and sidewalls as cast steel. Extremely thin sections tend to cause failure due to bulging followed by cracking, while thick sections often fail to give service in proportion to their greater cost, especially when operated at high temperatures and high output. In other words, the life of a pot is not directly proportional to its thickness, except possibly within narrow limits. The premature failure of thick pots is probably often due to the greater temperature difference between the inner and outer surfaces. Pressed pots of either steel or special alloy are necessarily of quite uniform section throughout.

Furnace Design—Lead baths are generally fuel fired with either oil or gas. Electrically heated units, in which the heat is applied by means of resistors surrounding the pot, are also in use. The principal advantages of electric heat consist of exceptionally long pot life and cleanliness. It is especially well adapted for use in the machine shop. The following discussion, however, is confined to fuel fired baths.

The design of the furnace and especially of the refractory setting, which supports the pot and forms the combustion chamber, should receive the most careful consideration. Proper location of burners and vents, adequate combustion space, correct vent area, length of flame travel, location of splash brick, and height of combustion chamber are all items which, if neglected, may result in unsatisfactory and costly operation.

Lead Bath Coverings—(Solid Coverings)—As previously stated, lead is readily oxidized by the air at all temperatures when molten, and must be covered with some suitable material, in order to avoid excessive lead loss and dirty stock. Wood charcoal, corncob charcoal, charred nut shells, charred leather, coal coke, and petroleum coke are some of the materials in commercial use as pot coverings. Hardwood charcoal, size No. 3, such as is used in the manufacture of carburizing compounds, is one of the best coverings, but is not always the most economical. In determining the most suitable covering, a great deal depends on the nature of the work and the temperature of the operation. In hardening transmission gears, the best covering obtainable is generally none too good, while in hardening axle shafts which are to be later drawn in lead, coal coke, or the cheapest grade of charcoal screenings, will answer the purpose.

The action of the carbonaceous coverings is both chemical and mechanical. Their efficiency depends, to a great extent, upon the rapidity with which they burn, and the temperature at which burning starts, sometimes called the "kindling temperature." The chemical action is due to the reducing effect of CO gas, which is

generated by the combustion of the covering. Below the kindling temperature, no CO is formed and the protective effect becomes entirely mechanical. Coal coke has such a high kindling temperature that it is practically useless in the tempering range, although it makes an excellent covering for some classes of work at the higher temperatures. Wood charcoal has a much lower kindling temperature, somewhere in the neighborhood of 850°F., and will protect the lead much less effectively at 800 than at 900°F., in spite of the fact that the tendency of lead to oxidize increases rapidly with temperature. The size of the covering must also be considered and depends largely on the nature of the job. Sizes much larger than No. 3 charcoal are generally unsatisfactory.

Depending on the nature of the work, the kind of covering employed, and the temperature of the operation, the bath must be skimmed more or less frequently. The coverings burn to an ash, which collects rapidly and interferes with the action of the CO gas. Moreover, the protective effect is never perfect and a certain amount of oxide will always form, even under the best conditions. This ash and oxide must be removed and replaced with new material every so often or trouble will result.

Prevention of Lead Adherence—In order to more effectively prevent adherence of lead, the stock is sometimes coated with a thin film of salt or some other material, before being placed in the pot. The salt is applied by dipping the parts in a hot saturated brine solution, which dries quickly and leaves a light deposit of NaCl. This method has been used extensively on parts which are difficult to keep clean, and is applicable at all temperatures below 1475°F., the melting point of NaCl. Numerous other washes, such as calcimine and emulsions of lampblack in kerosene, have been used for the same purpose.

At low temperatures, below the kindling point of the covering, the question of cleaning the stock often becomes a serious problem. This difficulty has been overcome by dipping the stock in molten caustic soda immediately following its removal from the lead and then quenching in water. The result is perfectly clean work and a large saving in lead. The caustic soda pot is held at a temperature slightly below that of the lead. Sodium nitrate has been successfully used for the same purpose.

Liquid Coverings—Molten salts of suitable composition make effective coverings, but are generally more expensive than solid coverings. Cyanide mixtures are very efficient, but their cost for large production is prohibitive. Mixtures of NaCl, Na₂CO₃, and K₂CO₃ have been used successfully on small units. Salt coverings have the advantage of producing exceptionally clean work and keeping the lead loss to an extremely low figure. The salt consumption, however, is usually a source of considerable expense. Many salts, other than those mentioned above, have been tried without success. Caustic soda, which might be thought suitable for low temperatures, causes a gradual oxidation of the lead, while sodium nitrate is still worse in this respect. Most of the mixtures of chlorides and carbonates tend to decompose and form infusible products which are very objectionable.

A decided objection to the use of salt covering on large pots is the great amount of heat radiated from the surface of the bath, which results in bad working conditions for the operators and lowers thermal efficiency. The solid coverings have a marked blanketing effect, which is almost entirely absent with the salts.

Pot Failures—With properly designed and operated units, pot failures are due to three general causes: Porosity, cracking and oxidation. Cast iron almost always fails by cracking. Cast steel usually fails from porosity, and from oxidation, as a secondary effect, when blow holes open up as the metal scales away. Failures with cast steel pots are seldom due to cracks. Cast alloy pots usually fail from cracking, and in many cases from porosity. They suffer very little from the effects of oxidation, except where metal segregation occurs. Pressed steel pots nearly always fail from oxidation, and pressed alloy pots usually from oxidation or cracking.

Lead Poisoning—There have been many erroneous statements made in regard to lead poisoning. According to some of the older authorities, the very atmosphere in the neighborhood of a lead bath was supposed to reek with noxious and poisonous vapors, which would inevitably result in the death and destruction of all who lingered in the vicinity. Such statements to the contrary, lead poisoning is very seldom encountered in any modern shop. Two simple precautions are necessary: Keep the waste gases from the combustion chamber out of the shop by employing suitable

hoods and stacks, and keep finely divided lead oxide out of the atmosphere. Operators have suffered from lead poisoning by continually breathing the products of combustion, which often carry lead compounds because of accumulations of lead under the pot. Poisoning has also resulted from lead oxide in the form of dust, which was continually thrown into the air during a hammer straightening operation on shafts. Removal of this oxide by quenching the shafts from the tempering bath eliminated the trouble. The surface of a lead bath does not give off any injurious vapor at temperatures of commercial operation.

Caution—Material to be immersed in a lead or salt bath with any degree of safety must be entirely free from moisture. When moist material is immersed in a molten bath, the moisture is instantly changed into steam, thus causing a violent eruption of the bath, which may burn the operator severely.

Methods of Operation—Lead pot furnaces may be operated by either the batch or continuous methods. For tempering, the former is the more satisfactory, while for hardening, both methods are successfully employed. In using the batch method, the pot is filled to its full capacity and the work completely removed as soon as the desired temperature is reached. It is generally necessary to shut off the burner before removing the work, but in some hardening operations, if charging and discharging are sufficiently rapid, the burner can be allowed to remain open. With the continuous method, the bath is held at the desired temperature, part of the load being removed and replaced with cold work at stated intervals. Automatic handling of the stock has been applied to lead baths with a certain degree of success but many difficulties have been encountered which are not met with in oven furnaces. Parts requiring local heating are often quite readily handled with rotary fixtures in round pots, or with chain conveyers in long rectangular pots.

Applications—While the lead bath still has a definite field of utility, it has been largely replaced in the treatment of many parts by the more economical automatic oven furnace, which has been so highly perfected in recent years.

The lead pot is extensively used for local hardening and tempering. Many jobs requiring local heating cannot be satisfactorily handled in any other way. By proper manipulation, it is possible to so treat a bar of steel that it will have a number of alternate hard and soft sections between the two ends. Heating can be much more effectively localized in lead than in any of the salt mixtures. For parts which must be free from scale, the lead bath is extremely useful. In tool hardening, the lead bath has many applications. It is used for hardening broaches, reamers, drills, and numerous other tools. It makes an excellent quenching medium for high speed steel, as originally developed in the "Taylor White" process.

Salt Baths*

General—By the term "salt bath" is meant a bath, composed of one or more salts, which is designed to form a heating medium inert to the work, and which is intended to impart neither a hard nor a soft surface to metal, but to produce work having the same chemical composition from surface to interior as it had before heating.

The value and economy of a salt bath depend upon its application to suitable jobs and upon its use within the limits of temperature at which the salt mixture operates at highest efficiency.

Salt Bath vs. Oven Furnace—(1) The bath tends to heat work more uniformly than do most ovens. The work is ordinarily suspended in a bath, but is usually laid on the hearth in an oven; and the nature of a bath naturally eliminates contact of cold air with the work, whereas many oven furnaces are not air tight. If an oven furnace is air tight, and if the work is suspended therein or otherwise arranged so that heat absorption is equal on all surfaces, there is no reason why the heating will not be at least as uniform as in a salt bath.

(2) Salt baths, if properly maintained and operated, eliminate scaling. This is an advantage of salt baths over air furnaces. Controlled atmosphere furnaces may, however, equal salt baths in this respect. Salt adhering to work removed from a bath also helps to prevent scaling while cooling or during transfer to the quenching medium, although a salt which does not dissolve quickly in the quenching medium may hinder quenching.

(3) Salt baths, as here considered, do not carburize, but in general tend to decarburize steel, the activity of a bath depending upon the temperature at which it is operated. It is possible to obtain salt baths which, if used properly decarburize so slightly that the soft skin cannot be detected after quenching. Air furnaces may be carburizing, decarburizing, or acceptably neutral, depending on the atmosphere within the furnace.

(4) Salts heat the work more rapidly than do air furnaces. This may be either an advantage or a disadvantage, depending on the application and on the design of the parts. The rapid heating, together with the proximity of the heating medium and the atmosphere, makes salts usually more desirable for local heating.

(5) The salts themselves and the pots containing them are items of expense not encountered in oven furnace operation.

(6) Salts carried over with work to a quenching bath may change the composition of the quenching medium. This does not occur with mineral oil, but may with water or any liquid in which the salts in question are soluble.

(7) Work must be dry and preferably slightly preheated, before immersing in a salt bath.

(8) Salts flux with many refractories at high temperatures. This means that furnace maintenance may be more costly if salt baths are used.

(9) The question of warping and cracking of work heat treated in a salt bath is one to which no general answer can be given. In some cases, where the work is preheated and, due to its nature, may be heated more uniformly in a salt bath, warping and cracking may be less with a bath than with an oven. On the other hand, where slower heating is desirable, a well designed oven furnace may give better results.

Salt vs. Lead Baths—(1) Because of the solubility of salt in water, it is usually more easily cleaned out of holes and depressions in work than lead.

(2) Lead may be melted and heated more rapidly than can salt baths, owing to the higher conductivity of the former.

(3) Work floats on lead, and usually must be held firmly in place, whereas metals need merely be suspended in salt baths.

(4) Most salts are to some extent hygroscopic, and must be stored in air tight containers when not in use.

(5) Aside from its tendency to oxidize, lead maintains a stable composition, whereas most salts undergo some decomposition during use. When a salt bath is used for hot quenching, the high temperature of the quenched work may decompose some of the bath constituents, such as nitrite, which must be periodically replaced to maintain the desired composition.

(6) Lead is neutral to most refractories, though lead oxide is not.

*Prepared by the Subcommittee on Salt Baths. The membership was as follows: W. P. Eddy, chairman; E. F. Davis, W. J. Harris, H. D. Ford, and J. H. McCadle.

(7) Lead costs more initially than most salts.

(8) Less mechanical (drag out) loss is suffered by a properly protected lead bath than by salt baths during operation. On the other hand, the salt adhering to work may be classed as a protective coating. Salt is more easily removed than lead due to its solubility in water.

(9) The surface of a lead bath must be protected from the atmosphere.

(10) Lead heats work more rapidly than do salt baths; hence lead is usually preferable for local heating.

General Characteristics of Salt Baths—The ideal salt bath should be inert to the metal heated in it; should not change in composition or form a sludge; should not fume corrosively; should clean easily; should not pit or corrode either the work or the bath container; should be thinly fluid at the operating temperature; should be nonhygroscopic; should not promote rusting of work subsequent to heat treatment; and should be low in cost.

The perfect salt bath, however, has not yet been discovered. Practically all the salts used for heat treating are hygroscopic to some extent. All adhere to the work when it is removed; the amount of drag out varies, of course, with the viscosity of the bath and with the shape of the work, but is usually between 4 and 24 oz. of salt per hundred lb. of work. There is always a corrosive action at the surface of a salt bath, affecting containers, thermocouple tubes, hooks, and partly immersed work; this action is more severe the higher the temperature.

Classification of Salt Mixtures—For convenience in the consideration of specific salt mixtures, we may divide them into three groups. Low temperature salts are used for tempering, and for quenching carbon or low alloy steels. Medium temperature salts are used for heating the same steels for hardening, normalizing or annealing, and for quenching high speed steels. High temperature salts are used for heating high speed and certain other high alloy steels for hardening.

Low Temperature Baths—Low temperature salt baths are composed of nitrates and nitrites of the alkali metals. Sodium nitrate, sodium nitrite and potassium nitrate are the salts most commonly used. Sodium nitrate, melting at 586°F., may be used at temperatures above 650°F. The eutectic mixture of potassium nitrate (56%) and sodium nitrite (44%) melts at 295°F. and may be used at 325°F. or above. A mixture of potassium nitrate (51.3%) and sodium nitrate (48.7%) melts at 425°F. and is suitable for use above approximately 475°F.

The maximum temperature recommended for any of these low temperature baths is 1100°F., as at higher temperatures they attack the work and the bath containers. Local overheating of the bath container must not be permitted, else failure will occur. Nitrates and cyanides react together violently, when hot, and the two should be kept apart; serious explosions have occurred as a result of failure to observe this precaution.

These mixtures are commonly used for tempering all types of steel. The potassium nitrate and sodium nitrite mixture given above is the most desirable for general purpose work, as it has the widest temperature range of usefulness. However, if the low temperatures are not to be used, one of the other mixtures will be cheaper. Work should be thoroughly cleaned of oil, salt from brine, scale, or soot, before immersion in any of these tempering baths. Otherwise, contamination of the bath will occur, resulting in thickening, sludge formation, increased drag out, lowered efficiency, and difficult cleaning after tempering. Any of these mixtures, if uncontaminated, will dissolve easily in water, and work may be easily cleaned by simple washing. If desired, work may be cooled in oil after tempering, and can then be cleaned quickly in an alkaline solution.

In addition to the above mentioned use, these baths may be used, either alone or with additions to other salts, for blueing and blacking steel. To obtain a black, it is necessary to heat to 900-1000°F. Considerable skill and experience may be required to produce uniform blue or true black colors.

Another increasing use of nitrate baths is in the heat treatment of the strong aluminum alloys. The solution treatment is performed by quenching from temperatures, varying with the alloy, between 900 and 1000°F. Precipitation treatment consists of heating for considerable periods at 300-400°F. Large sizes (% in. and over) of duralumin rivets may be heated in these baths for hot riveting. Unless the salt is completely removed afterward, however, it may accelerate corrosion.

These baths may be used for quenching carbon and low alloy steels. The bath may be maintained at any temperature between 300 and 1000°F., depending upon the hardness and physical properties required in the quenched work. Some decom-

position of the bath constituents may occur due to the local action of the hot work being quenched, and some pitting of the work may occur. The intensity of these actions depends on the size of the work and its temperature before quenching.

Medium Temperature Baths—Salt baths in the medium temperature class are used for heating carbon and many alloy steels for normalizing, annealing, and hardening; for quenching and tempering high speed steels; and for heating brass, bronze, nickel silver, copper, gold, and other nonferrous metals and alloys for bright annealing treatments.

Salt mixtures for use in the medium temperature range are perhaps more varied in composition than are the low temperature mixtures; but, in general, the mixtures are eutectics and are composed of chlorides, or of chlorides and carbonates.

The chloride carbonate mixtures (such as 50% potassium chloride and 50% sodium carbonate, which melts at 1085°F.) are satisfactory for heat treatment of nonferrous metals. Carbonates in a salt bath tend to decarburize steel. Such mixtures are sometimes used for heating steel, however, with additions of sodium cyanide to prevent formation of soft skin on steel parts. The action of the cyanide is to replace some of the carbon lost during heating with nitrogen. The desirability of this practice is often questionable, especially with steels of over 0.75% carbon. Addition of cyanide to a bath may, however, improve ease of cleaning of work.

Baths consisting of chlorides only are generally preferred for heating steel. The lowest melting chloride mixtures contain calcium chloride (for example calcium chloride 67% and sodium chloride 33%; melting point 940°F.). Calcium chloride, however, because of its deliquescence and its tendency to corrode work, is in general not a desirable constituent. The alkali chloride mixtures (for example, potassium chloride 56% and sodium chloride 44%; melting point 1220°F.) are the most easily handled.

However, even the chloride mixtures, though originally inert to steel, gradually oxidize, when molten, to oxychlorides, then oxides or carbonates. As a result, these mixtures, also, may decarburize steel after some use. Additions at regular intervals of $\frac{1}{4}$ – $\frac{1}{2}$ % of the weight of the bath of a suitable "rectifier" will usually counteract the tendency of the bath to decarburize. The rectifier (boric acid, fused borax, or boric oxide) converts oxides and carbonates in the bath to stable metaborates, which usually form a sludge that can be removed and discarded. Such rectifiers are of no value when added to a chloride-carbonate bath; they may advantageously be used only in chloride mixtures.

The medium temperature bath mixtures can be used from approximately 100°F. above their melting points up to about 1650°F.

High Temperature Baths—The high temperature baths are generally used in the temperature range of 1800–2400°F., primarily for hardening high speed steels. The salts used in these bath mixtures are barium chloride, borax, sodium fluoride, silicates, and occasionally magnesia or lime. Rectifiers containing ferrosilicon have also been used. These baths are not eutectic mixtures, but are glasses; they have no sharply defined melting point, but soften gradually when heated. The melting range is usually between 1600 and 1900°F.

Some of these baths, when new, are not inert to steel, but become satisfactorily so after some use, so that high speed steels can be heated without occurrence of scaling or decarburization. In some cases, trouble may be experienced with edges of fine tools dissolving or "washing away."

For preheating, the same salt is sometimes used, maintained in or just above its melting range; the work should be held in the preheat bath until the salt runs off freely when the work is lifted from the bath. In order to shorten the time in the preheat bath, an additional semimuffle or muffle heating should be used, in which the work is heated to 1000–1200°F. before transferring to the salt preheat. A single preheat of the muffle or semimuffle type, as in air furnace practice, may be substituted for the double preheat, but scaling of work usually makes this undesirable. Modern practice usually involves the use of a chloride or other salt mixture of lower melting range for the preheat bath.

Perhaps the greatest disadvantage of the high temperature bath mixtures is that none of them are easily cleaned from the work. It is almost imperative that a salt quench be used. The salt quench consists of an added unit in the system in the form of a pot containing a chloride-carbonate bath, with or without cyanide, maintained just above its melting point, and preferably below 1200°F. Such a bath reacts chemically, with some sputtering, with the high temperature salt adhering to the work as it is lowered into the quench, the reaction being between the carbonates or cyanides in the quenching bath and the high temperature salt. The prod-

ucts of the reaction form a heavy sludge in the quench pot. This sludge must be frequently removed and thrown away. The action of the quenching salt has an important bearing on the quality of work. While a quenching mixture containing a large proportion of carbonate is desirable from the cleaning standpoint, a large excess of carbonate may cause formation of soft skin on the work, through the decarburizing action previously noted. Quenching in a chloride mixture or in oil or air gives greatest freedom from soft skin, but work quenched in any of these media is extremely difficult to clean. Immersion in vigorously boiling 10% sodium cyanide solution for $\frac{1}{2}$ hour or more, followed by wire brushing, is often used to clean work. Dipping the work in molten caustic soda at 1050°F., after tempering, is usually helpful.

Salt Bath Operation—The most important general rule of salt bath operation is: Do not allow the bath to become contaminated with anything. This applies to salt baths in all temperature ranges.

Pure salts should be used in all mixtures. Sulphates are particularly undesirable in all mixtures, and nitrates should not be present in medium or high temperature baths. To eliminate small amounts of these corrosive impurities from a bath, add about 5% of the weight of the bath of clean, dry cast iron chips, preferably while the bath is near the top limit of its temperature range, stir well, allow to settle and remove the sludge formed. Ferrosilicon may be used for this purpose in high temperature baths. If a rectifier is to be used, it will serve also to eliminate sulphates and nitrates. The best baths are usually made by specialists in salt bath manufacture.

Heat salts slowly while solid; they are all poor conductors of heat, and the rate of heat absorption is therefore limited when there can be no circulation. An attempt to melt too quickly only results in overheating of the pot with consequent short life, and possible overheating of the salt adjacent to the pot.

When additions of salt are to be made, it is safest to place the required quantity on top of the solid salt before melting. If this is not practicable, because of 24 hour operation or high drag out which necessitates more frequent additions, be sure the added salt is dry.

A salt having low melting point is desirable when large work is to be heated, as the immersion of a large mass of metal lowers the temperature so much of the adjacent salt that a thick coating of solid salt will form on the work. If possible, large work should be preheated up to the melting point of the bath, then immersed with the bath just above its melting point, and the bath and metal slowly heated to the desired temperature.

Melting point of the bath is not usually important for small work, provided the melting point is not too near the operating temperature. Small pieces can be immersed, preferably after some preheating, with the bath at the operating temperature. If many pieces are to be heated at the same temperature, it is advisable to establish a semicontinuous procedure, immersing a small quantity immediately after removing an equal quantity.

It is advisable to remove the thermocouples, at the end of a run, before the salt freezes.

Salt baths weigh from 100 to 150 lb. per cu. ft., molten.

Salt Bath Furnaces—Oil fired pot furnaces are satisfactory in large sizes, though not, as a rule, so desirable as other types in smaller units, because of the long flames which are characteristic of oil burners. Gas firing is usually satisfactory, provided furnaces are properly designed.

Electric pot furnaces of several types have been more or less successfully used. A resistance furnace, with metallic heating elements surrounding the pot, may be used for low and medium temperature operation, provided care is taken to keep salt away from the resistors.

The direct resistance type of furnace has been used with some success. Two or more electrodes are lowered into the bath, or the pot can serve as one of the electrodes. The salt is heated by the current passing through the bath itself. Special means must be taken in this furnace to start the melting of the solid salt, and care must be taken during melting to prevent local overheating of the salt. After the bath is entirely molten, however, this type of furnace is inherently very efficient, as the heat is generated where it is wanted.

A few generally important points of design and operation, which apply more or less to all types of bath furnaces, follow:

1. Apply heat as near the top of the pot as possible, in order to obtain more uniform temperature and to start melting solid salt at the top. All molten

salt baths are hotter near the bottom than at the top, because of the high radiation losses from the surface. As all salt bath materials expand when heated, melting first near the bottom causes heavy pressure to be applied to the pot, with resultant deformation and early failure.

2. In fuel fired furnaces, the flame should not impinge upon the pot. Cylindrical pots, with tangentially placed burners near the top, should be used whenever possible. The furnace should be vented at the bottom for the removal of flue gases. It sometimes pays to conduct the waste gases into an adjacent chamber where they may be used for preheating work.
3. Bath materials and the fumes therefrom should be kept out of combustion or heating chambers, as refractories and heating elements are readily attacked by salts.
4. Combustion chamber atmosphere is important in relation to pot life. With steel pots in fuel fired furnaces, a slightly reducing or soft flame is desirable. All openings should be plugged when the furnace is shut down, to prevent circulation of air which would scale the hot container.
5. Furnaces should be of sufficient capacity to prevent a large drop in bath temperature when work is immersed, and to allow all work to be immersed without touching or nearly touching the sides or bottom of the pot.
6. To conserve heat, pots should be covered whenever possible.
7. If work is to be totally immersed in a salt bath, wire mesh baskets may be used for small parts, and larger work may be suspended on a hook by means of soft iron wire. The wire should be well annealed and must be twisted lightly with pliers in order to insure against work being lost in the pot when the wires become hot and sag.
8. A spare pot should be kept near every bath furnace. A small leak in a fuel fired furnace will quickly be detected, as white "smoke" will come out of the flue gas exhaust vent. Time will then usually be available for the molten bath material to be ladled into the new pot, after which the failed pot can be easily removed and the newly filled pot let down into the furnace, with little loss of time.

Temperature Measurement—Mercury thermometers made of metal may be used in low temperature tempering baths. These instruments are cheap and sufficiently

Melting Points of Salts

Salt	Melting Point, °F.	Salt	Melting Point, °F.
Barium chloride	1784	Potassium hydroxide	716
Barium fluoride	2336	Potassium nitrate	631

Calcium fluoride 48, magnesium fluoride 52	1738

accurate and durable at the low temperatures involved, though they do not permit the use of automatic control. For higher temperatures, thermoelectric pyrometers are universally used.

The protection of thermocouples is important in bath heat treating. The wires must be protected by a metal tube which is not rapidly decomposed by the bath, to prevent contact of the bath material and the couple. Such contact not only results in shortened thermocouple life, but also immediately causes false readings. The hot junction of the thermocouple should always be immersed in the bath to the same depth as is the middle of the work, and should be placed close to the work and as far from the side of the pot as possible.

Quenching Equipment*

Fundamentals of the Quenching Operation—The type of equipment used for quenching depends first upon whether the quenching medium to be employed is a solid, a liquid, or a gas.

In designing or selecting equipment for quenching in liquids such as oil, water, and aqueous solutions, the fundamentals of the quenching operation must first be taken into consideration.

The objective of quenching is to cool the steel at the desired rate. The rate of cooling produced depends upon the temperatures, mass and shape of the steel, the temperature, volume, inherent characteristics, and speed of circulation of the quenching medium or speed of movement of the steel being quenched.

With reference to the effect of the inherent characteristics of the quenching medium, it may be said that when a piece of hot steel is immersed in a liquid such as water, oil, or aqueous solutions, the liquid coming into direct contact with the hot steel is first vaporized. Heat is absorbed by raising the liquid to the boiling point and then by converting it into a vapor. Both the specific heat and the latent heat of vaporization of the liquid are factors in determining the speed of cooling produced. The vapor thus formed usually recondenses and gives up its heat before it reaches the surface of the bath. As the conductivity of the liquids is relatively low, conduction of heat through the quenching bath probably is a minor factor in determining the speed of cooling. The relative merits of different media are discussed in another section of this article.

With any given quenching medium, the speed of cooling may be varied by changing the speed of movement of the hot steel or the speed of circulation of the quenching medium.

The motion of the steel may vary from zero to any desired rate. Small articles are frequently quenched by allowing them to drop through the bath to the bottom of a basket or onto a conveyor in the bottom of the quenching tank. In the former case it is preferable that the distance to the bottom of the basket be great enough so that the pieces being quenched will be relatively cool before they reach the bottom. When conveyors are used the steel is kept in motion after it falls upon the conveyor. In any case, however, the steel should not be allowed to pile up in the basket or on the conveyor before it is properly cooled. A variation of the type of motion produced by gravity consists in rolling or skidding the work down rails or plates through the quenching bath. This produces a slower speed of travel but increases the length of time that the work is in motion before reaching the bottom.

Small pieces held by hand tongs and larger ones held by hoists are frequently kept in motion until reasonably cool. Moving conveyors are employed for pieces varying in size from that of small bolts to automotive front axles. A variation of the conveyor method of producing motion consists of a rotating screen barrel with a worm inside which keeps the work constantly tumbling over and advancing forward. This is particularly advantageous in handling small parts on a quantity production basis.

The simplest type of circulation of the quenching media is that produced automatically by the action of the hot steel in vaporizing and heating the bath in its immediate vicinity. The tendency is for the vapor to rise from the top of the steel and for fresh liquid to rush in to the bottom. The speed of such circulation depends upon the characteristics of the quenching medium. At best this is likely to produce nonuniform cooling. If the design of the piece is such as to allow the formation of vapor pockets, the quenching becomes even less uniform.

The next and most common type of circulation consists of the flow of the liquid into, through, and out of the tank. Usually the inlet is near the bottom and the outlet near the top of the tank. The rate of circulation thus produced is usually not extremely rapid, but is nevertheless quite an important factor in governing the speed of quenching.

Another type of circulation of the quenching medium is effected by means of mechanical agitators or propellers, which produce rapid circulation of the liquid

*Prepared by the Subcommittee on Quenching Equipment. The membership was as follows: H. B. Knowlton, Chairman; W. O. Owen, C. D. Steffens, and C. H. Stevenson.

This article not revised for this edition.

within the quenching tank. This may be arranged so as to provide a rapid flow of the medium around the piece being quenched. This may supplement the flow of liquid into and out of the tank.

Another and most effective method of controlling circulation is involved in what is commonly known as "pressure quenching". This method forcing the quenching medium directly against the steel under pressure. Either open or submerged pressure jets may be arranged so as to produce either uniform cooling or very rapid cooling of some particular locality. Specially designed pressure quenching fixtures frequently solve the problem of uniform quenching of parts of intricate design.

In selecting or designing quenching equipment some attention must frequently be given to minimizing warping and distortion, which results from nonuniform cooling. Any method which produces more uniform cooling will help minimize warping. For example, a shaft which is revolved in a horizontal position in the quenching bath will warp less than one which is held stationary in the same position. Similarly, a properly designed pressure quenching fixture will produce less warping than free hand quenching.

Another method of minimizing warping and distortion consists in mechanically holding the article during quenching. As an example of this type of equipment, may be mentioned the quenching machine commonly used in the hardening of automotive bevel ring gears. This consists essentially of an expanding mandrel and a set of perforated dies which hold the gear under pressure during quenching. The quenching medium is forced under pressure to all parts of the gear during quenching.

Volume of Quenching Medium—It is obvious that heat removed from the steel being quenched is absorbed by the quenching medium, and consequently causes an increase in the temperature of that medium. As an increase in the temperature of the quenching medium produces a different speed of cooling, it is usually desirable to control the temperature of the quenching medium within certain desired limits.

Rise of temperature above the allowable maximum can be prevented only by bringing a sufficient volume of the quenching medium into close enough proximity to the steel to be effective in removing heat. This statement holds true regardless of whether the circulation is natural or produced by artificial means. (See the following discussion of "Cooling the Quenching Medium".)

Minimum Volume of Quenching Medium—The theoretical minimum volume of quenching medium which must come within the effective proximity of the steel in a given length of time may be calculated with the use of the following formula:

$$\frac{W' \times SH' \times (T' - T'')}{SH'' \times W'' \times TR} = \text{cu.ft. of quenching}$$

medium which must come within an effective proximity of the steel in a given time.

In which:

W'	=	Weight of material quenched.
SH'	=	Mean specific heat of material quenched.
T'	=	Temperature of heated material.
T''	=	Temperature of material at time of removal from quenching tank.
SH''	=	Specific heat of quenching medium.
W''	=	Weight per cu.ft. of quenching medium.
TR	=	Allowable temperature rise of quenching medium.

Particular attention is called to the statement that this volume must come within the effective proximity of the steel. For example, this formula can be used for calculating the size of a tank for batch quenching without forced circulation, only in case all of the liquid in the tank comes into close enough proximity to the steel to absorb heat, or in case the rate of addition of hot steel to the tank is slow enough so that the heat absorbed will be conducted or conveyed to other portions of the tank. In this connection, it must be remembered that the quenching medium in the bottom of the tank below the level to which the hot steel is submerged will remain cold, and consequently, cannot be considered in the effective volume of the tank.

In applying this formula to the calculation of volume to be delivered by pumps to quenching tanks, it must also be remembered that all of the volume delivered to the quenching tank may not be effective in removing heat from the steel.

Consequently, it is recommended that the above formula for theoretical mini-

mum volume be multiplied by a liberal safety factor in calculating size of tanks and capacities of pumps. It is a safe recommendation that pumps and tanks should be figured oversize rather than undersize.

Cooling of the Quenching Medium—Method of cooling the quenching medium depends very largely upon the type and quantity of work to be handled. The various methods of cooling may be classified briefly as follows:

1. *Tank Cooled by Direct Radiation*—In cases where the production is very small, a simple tank without any special means of circulating or cooling may be sufficient. The tank should be quite large in proportion to the quantity of heat to be removed per unit of time. Cooling is purely by radiation from the surface and the walls of the tank. This type of tank is frequently used in tool rooms, which do a limited amount of hardening of small tools each day. In case the quenching medium is oil, the temperature should be checked occasionally and not allowed to become too high as there is a decided fire risk if the temperature of the oil approaches its flash point.

2. *Cooling of the Quenching Medium in the Tank Without Forced Circulation*

(a) The method of surrounding the quenching tank with a large water jacket with or without circulation of the cooling water has the advantage of low initial cost. The rate of transmission of heat from the tank to the water jacket is relatively low. The larger the tank in proportion to the wall surface, the lower will be its efficiency. Consequently, this design is limited to small installations.

(b) The quenching tank may be supplied with coils through which cold water circulates. The efficiency of this method depends upon the cooling surface of the coils in proportion to the volume of the tank. Efficiency is relatively low, but may be somewhat greater than that given under 2-a. This design is also limited to comparatively small installations.

(c) The quenching tank may be equipped with coils through which is circulated an externally cooled liquid, such as water or brine. This method is somewhat more efficient than those previously mentioned, but is more expensive as it introduces a pump and an external cooling system.

3. *Circulation of the Quenching Medium Between the Quench Tank and an External Cooling System.*

This type of equipment may be subdivided according to the type of external cooling system employed.

(a) A large storage tank which may or may not be supplied with cooling coils requires a large quantity of quenching medium in the storage tank in proportion to the size of the quenching tanks. If the storage tank is not provided with cooling coils, the temperature attained by the liquid will depend somewhat upon the surrounding temperatures. This method has the advantage of simplicity, and may be advantageous where land values are low, and large storage tanks or cisterns can be built economically.

Aside from its cooling function, a storage tank acts as a common reservoir for all of the quenching tanks in the hardening room, and permits drainage of at least a portion of these tanks and utilization of the oil in the other tanks.

(b) Air cooled coils or pipes may be supplied through which the quenching medium is circulated. This requires a large surface area, as the rate of transmission of heat from the pipes to the air is relatively low. The final temperature of the quenching medium is limited by the air temperature.

(c) The method of spraying or aerating the quenching medium is usually employed in conjunction with cooling coils or tanks. This is the most efficient of the air cooling systems, as the liquid when divided into a spray offers a large cooling surface in proportion to its volume. This method may be open to the objection of a fire hazard if used in the cooling of hot oil. Space and location of this type of equipment must be carefully considered.

(d) Tanks may also be equipped with an external cooling system of tubes, through which the quenching medium circulates. The efficiency of this method will depend somewhat upon the ratio of the cooling system of the tubes to the volume of the liquid passing through them. When used in a shell and tube type unit with water as the cooling medium, the shell side using the water must be accessible for cleaning. If the shell side becomes covered with scale, the efficiency of

the unit is decreased. It is advisable, therefore, to use a water which produces the minimum amount of scale, or to resort to frequent cleaning. Careful design of the cooling unit is recommended.

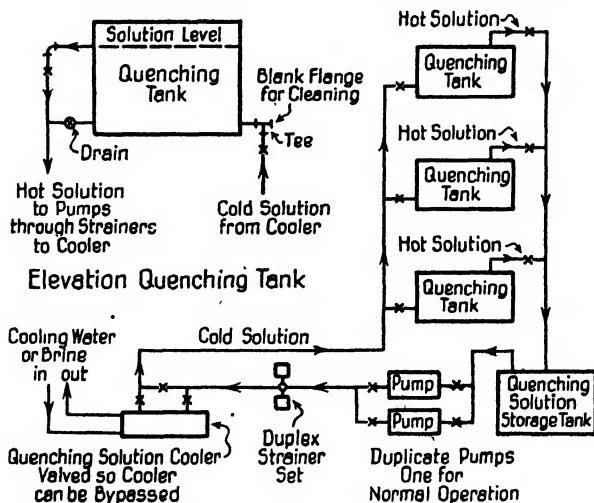

(e) Another external cooler consists of tubes over or around which the quenching medium is circulated. When such units are properly designed, their efficiency should be relatively high as the quenching medium passes in a thin film over a comparatively large cooling surface. Where water is used as the cooling medium, it is necessary that the cooler be designed so as to permit easy removal of scale from the interior. This method has the advantage of efficiency and compactness, but the disadvantage of a higher initial cost.

(f) There are a number of specially designed commercial coolers, which usually involve one or more of the cooling principles previously mentioned. These usually are designed for a close approach between the temperatures of the quenching medium and the cooling liquid. They have an advantage of compactness and efficiency, but the disadvantage of higher initial cost.

(g) When water is used as the coolant, the lowest temperature which can be attained by the quenching medium will be slightly higher than that of the water. When still lower temperatures are desired, it is necessary to use a refrigerating system. With proper design, any desired temperature may be produced by refrigeration. This method may also be used for cooling the quenching liquid to temperatures above that of tap water. The refrigerating system has the advantage of small size and maximum efficiency, but the disadvantage of high initial cost and comparatively high cost of operation and maintenance.

Safety Precautions—When oil is employed as the quenching medium, proper precautions should be taken to minimize the fire risk. The temperature of the oil in the quenching tank should never be permitted to approach the flash point. Fig. 1 shows duplicate pumps and strainers in the circulating system. This is very important as any breakdown of the circulating system might result in a serious fire.

In case of fire, the circulation of the oil should be kept up, or if possible increased in order to lower the temperature of the oil below its flash point. Oil fires start slowly and are usually readily extinguished if the action is prompt. It is often possible to extinguish them by merely stirring the oil in the quenching tank.

Note: Quenching Solution Storage Tank and Pumps to be located at lower elevation than other units.

Fig. 1—Typical piping arrangement showing a plan view of a battery of quenching tanks with external quenching solution cooler.

Smother covers, which can be quickly applied, are very satisfactory for small tanks and have been used to some extent even with large ones. A fire hose or a sprinkler system delivering water into an oil fire may spread the fire. Chemical

extinguishers are preferred. The chemical should be shot just above the surface of the burning oil—not into the oil—as the rapid vaporizing of the chemical beneath the oil might also spread the fire.

In designing an external cooling system, the specific gravity, viscosity, and thermal conductivity of the quenching medium should be taken into consideration. These have an effect upon the heat transfer rate obtained for any given solution and upon the amount of cooling surface required. The quantity of quenching liquid handled per unit of time, the range of temperature to which it is to be cooled, the amount and temperature of cooling water to be used, and the friction loss of both liquids which may be permitted, are also factors governing the design of the cooler.

Fig. 1 shows a typical layout of quenching tanks, and a cooling and storage system. This is given to show general principles only. The selection of quenching and cooling equipment will depend upon the quantity and type of work to be handled, value of land or floor space, and the cost of installation, operation and maintenance.

Quenching Media

By Howard Scott*

Requirements of Quenching Liquids Imposed by the Work to be Hardened—It is assumed that the function of the quenching is to produce martensite and hardening implies the formation of this constituent. Whether or not hardening occurs with a particular quench depends on the composition of the steel as well as on that of the quench. In recognition of the steel composition effect, it is necessary to distinguish at least between shallow and deep hardening steels in the discussion of quenching media. The shallow hardening steels are those of low or no alloy content while the deep hardening steels have a substantial content of alloying elements which increase penetration of hardening, notably chromium, manganese, nickel and molybdenum.

The fundamental property distinguishing shallow from deep hardening steels is the critical cooling rate. It is the slowest cooling rate measured at about 1020°F. at which a completely martensitic microstructure can be obtained. The temperature

specified is that of maximum rate of reaction in eutectoid carbon steel established by the Bain "S" curve.¹ The critical cooling rate for pure iron-carbon alloys when fine grained is extremely high, so high that effective hardening is impracticable. Even in plain carbon steels it is high, ranging from 126-360°F. per second. Evidently then an extremely fast quench is required for the hardening of shallow hardening steels.

Water under favorable conditions provides the surface cooling rate necessary for the hardening of carbon steels. It is in the neighborhood of 1800°F. per second. Surface cooling at this rate produces rates within the steel close to the maximum values theoretically possible of attainment; so there is little room for improvement in the cooling rate attainable with water. There are, however, other characteristics of water amenable to considerable improvement which are discussed later.

To cool as fast as indicated over the entire surface of the work is a difficult art. The success of the quench is determined within the first few seconds of immersion. If the cooling rate does not exceed the critical rate at any one point martensite will not form there. This constitutes a soft spot and soft spots seldom can be tolerated. Consequently, the need for extreme rapidity of surface cooling dominates all other factors in the hardening of shallow hardening steels.

Fig. 1—Observed cooling curve of center and of a point 0.16 in. from the surface of a long austenitic steel cylinder 2.00 in. dia. during quenching in agitated water.

Fig. 2—Observed cooling curve of center and of a point 0.16 in. from the surface of a long austenitic steel cylinder 2.00 in. dia. during quenching in agitated oil.

A necessary consequence of fast surface cooling is a high temperature gradient from surface to center. This gradient may exceed 70% of the temperature range, Fig. 1. It produces severe distortion in all but simple, symmetrical shapes having a low ratio of length to diameter or thickness. Shallow hardening steels, therefore, cannot be used in complicated shapes where distortion is objectionable. Furthermore, there is no possibility of changing this situation by choice of quenching medium if full surface hardening is required.

Despite the admirable properties of carbon steels, which include a low price,

*Engineer in charge of Metallurgical Section, Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa.

Prepared for the Subcommittee on Quenching Media. The membership of the subcommittee was as follows: A. L. Boegehold, Chairman; I. N. Zavarine, G. T. Williams, R. B. Queneau, and Howard Scott.

they cannot be used for complicated shapes where distortion must be avoided. In this case water quenching must be abandoned and a less active quench used which reduces materially the temperature gradient during quenching, Fig. 2. Certain oils perform this function admirably but are incapable of hardening shallow hardening steels of substantial size. A change in steel composition is therefore required with a change from water to an oil quench.

Oil quenching introduces entirely different problems from those of water quenching. Cooling rate gradients are no longer high so a completely martensitic surface shell can seldom be obtained over a fully pearlitic core. Usually there is considerable martensite at the center when the surface is fully hardened. If hardening is incomplete at the surface, there exist soft spots which may not be easily detected by a hardness test but which lower the toughness otherwise obtainable at the same hardness in their absence.

Since the cooling rate is slower the larger the section, the alloy content must be increased with increase in thickness of the section. Table I gives the cooling rates at the center of long cylinders during quenching in several media when the center temperature is 1022°F. relative to that of 1 in. dia. cylinder quenched in agitated water, rate for which is 101°F. per second.*

*Cooling rate for water at 65°F. is 3260°F./sec. over the range 1328-1022°F. and 810°F./sec. at 392°F.

With an oil quench the temperature gradients are considerably lower than with water, Fig. 1 and 2. The residual stresses determined by these gradients are also lower when hardening is complete at the center or nearly so. Though less intense than those of water hardening steels, these residual stresses are more dangerous because they are usually tensional at the surface of the work.

Residual stresses are "set" during the hardening transformation, A_r , but do not reach maximum intensity until the work is cold. It has been shown⁴ that their final magnitude diminishes with speed of cooling through the hardening transformation which starts under 750°F. and usually around 400°F. Thus slow cooling of deep hardening steels is important in this temperature range just as fast cooling is in the high temperature range where reaction velocity is high.

The advantage of slow cooling through the hardening transformation is easily demonstrated by quenching two 1 in. rounds of deep hardening tool steel in oil for 20 seconds then removing and cooling one in air, the other in water. The water cooled piece will crack explosively while the air cooled piece will not crack even though held without tempering.

Quenching in oil does not entirely prevent distortion. When the degree produced by oil quenching is objectionable, recourse is taken to air hardening. The cooling rate in air is much slower than in oil or water (Table I) so an exceptionally high alloy content is required. This means that a high price is paid for the advantage gained both in terms of metal cost and loss in machinability, though it may be well justified when applied to expensive tools. In this case danger of cracking is negligible.

Liquid metals and salts are also used as quenching media. A cadmium-tin alloy at 355°F. is intermediate between oil and water, as regards hardening ability and much superior to oil as regards residual stress generation. This is indicated by the position of this alloy in the left hand column of Table II and the low value in the right column relative to that in the left.

Table III

Maximum Sizes of Various Steels That Will Harden to C-50 Rockwell at the Center on Quenching in Oil and Water Together with Corresponding Critical Cooling Rate¹¹

S.A.E. No.	Grain Size	Maximum Diameter in Inches for		Cooling Rate at Center, °F./sec.
		Oil Quench	Water Quench	
1050	5-6	0.30	0.70	198
1045 + 0.2% Cr	6-8	0.40	0.90	134
T1340	5-8	0.70	1.20	76
5140	5-8	0.92	1.55	50
3145	5-6	1.15	1.80	38
4140	6-8	1.50	2.15	29
X3140	6-8	2.50	3.35	13
4340	3.40	5.00	6

Considerable variation from these figures is possible for each steel listed depending upon the grain size, method of manufacture, and composition. Cooling rates at center of rounds are those given by Scott¹² for water and oil quenching. Variation in severity of quench due to change of oil or water will change the above figures.

The major practical questions in connection with quenching media still remain. Will a particular size and composition of steel harden satisfactorily in water or oil? Data are not yet available to give a comprehensive answer, but Table III from a paper by Jominy and Boegehold¹¹ provides information on several important steels. In using such data it must be realized that there is a considerable variation between steels of the same nominal composition.

Liquids for Quenching Shallow Hardening Steels—Shallow hardening steels require extremely rapid surface cooling in the quench particularly in the temperature range around 1020°F. So far as is known a submerged water spray will give the fastest and most reproducible quench practicable. Such a quench, however, is distinctly limited in application to simple short objects which are not likely to warp. Because of the difficulty in obtaining symmetrical flow of the water relative to the work, the spray quench is highly conducive to warping. The ideal quench is one which will give the required surface cooling without any agitation of the bath.

It has been shown that concentrated sulphuric acid is a close approach to this ideal.⁵ Sulphuric acid is, however, too dangerous a liquid for practical use. Ordinary

tap water without agitation is a poor substitute which will not harden consistently with freedom from soft spots. The addition of ordinary salt (sodium chloride), however, greatly improves the performance of water. The manner in which salt improves the quenching properties of water can be seen clearly from the observations of Pilling and Lynch⁴ on various liquids and from Table V.

By taking cooling curves on a small specimen during quenching, Pilling and Lynch determined how the surface cooling power of the liquid changed with the surface temperature of the piece. Their observations are extremely significant in that they show three distinctive mechanisms of heat dissipation which have been verified by Speith and Lange.¹² Fig. 3 is a typical curve showing the three stages. These three stages of cooling have been described by Scott³ as follows:

Stage "A"—Vapor Blanket Cooling—In this, the first stage, a thin stable vapor film surrounds the hot metal. Cooling is by conduction and radiation through the gaseous film and is therefore relatively slow.

Stage "B"—Vapor Transport Cooling—Termination of the "A" stage is marked by wetting of the metal surface. Vapor forms copiously in bubbles and is carried away by gravity and convection currents to condense in cooler surrounding liquid. This is the fastest stage of cooling.

Stage "C"—Liquid Cooling—The "B" stage ends as the surface temperature of the metal approaches the boiling point of the quenching liquid. Vapor no longer forms so cooling is by conduction and convection and the temperature difference is greatly decreased. This mode of cooling is slower than that of the "B" stage.

Cooling in the "B" and "C" stages is in fair accord with Newton's law of cooling, that is the cooling rate is proportional to the surface temperature, which holds closely for short temperature ranges.³ In the "A" stage, however, cooling is at a nearly constant rate, which rate decreases somewhat with increase in the bath temperature.

Zavarine has noted from high speed photographs that rate of bubble collapse is relatively slow in the "A" stage and extremely fast in the "B" stage, of course vanishing in the "C" stage. Also that crystals of salt are precipitated momentarily during quenching in brine.

There has been much debate concerning the fundamental properties of liquids determining their quenching power. Those mentioned include: Thermal conductivity, viscosity, specific heat, heat of vaporization. Evidently which property is dominant depends on the stage concerned. Certainly boiling point is a major factor in the "A" stage, heat of vaporization in the "B" stage, and thermal conductivity in the "C" stage. Viscosity also contributes to cooling power both in the "B" and "C" stages. Each stage has an important part in determining the success of a quench. No distinction has been made between the "A" and "B" stages in the data of Table II, the left hand column representing a combination of both stages though the right column represents "C" stage cooling only. As a consequence of this overlap, water at 120°F. for example is placed below certain oils though its cooling rate in the "B" stage is just as fast as that of the LiCl solution. The three stages have been sharply distinguished in Table V.

The vapor stage, "A," is of most concern in water solutions. Cooling is slow in it and if it persists for more than a few seconds transformation will occur at A_r , producing soft spots. To avoid this occurrence the vapor stage must be suppressed or nearly so. Its duration may be measured in time units on the quenching curves of Pilling and Lynch giving a quantitative measure of the extent to which it is suppressed, Fig. 4. This figure shows that the duration of the vapor stage in water and water solutions increases rapidly with bath temperature. Hence the first rule of quenching is: *Keep water base quenching liquids cold, preferably under 70°F.*

Fig. 4 also shows clearly why salt is an advantageous addition to water. It reduces materially the duration of the vapor stage particularly at elevated temperatures. The liquid adjacent to the work is of course much above the average bath

Fig. 3—Typical cooling curve for the center of a small cylinder during quenching in still water at 137°F. It illustrates the three stages of surface cooling.³

temperature. From this viewpoint the best concentration is a saturated solution, about 26%, but there are objections to so high a concentration mentioned presently. A commonly used concentration is 10%, but under 5% is not recommended.

Other inorganic compounds are also effective in suppressing the vapor stage, calcium chloride and sodium hydroxide being used. As a matter of fact, most of the inorganic salts have a favorable effect in diminishing the duration of the vapor stage. A solution of common or rock salt in water of a concentration between 5 and 15% is a great improvement over pure water and is widely used. The concentration of salt in the bath may be checked with an ordinary hydrometer of suitable range. Relations between salt concentration and density measured by hydrometer are given in Table IV.

The presence of some other soluble materials in water is decidedly detrimental. Soap particularly extends the duration of the vapor stage cooling and therefore acts in the same manner as an increase in temperature of water, Fig. 4. It can easily overcome the benefit conferred by a salt addition and cause the formation of soft spots on quenching in brines. Soft spots form on carbon steels even when quenched in tap water at 70°F. Hence the rule: *Avoid contamination with soap of aqueous quenching liquids.*

Once the vapor stage, "A," is passed or suppressed, stage "B" cooling, in which water has its phenomenal cooling power, commences. Cooling power in this stage is not reduced materially by increase of bath temperature, but is reduced appreciably by salt additions. In fact a saturated solution of sodium chloride in water (about 25%) is no better than tap water at the same temperature, though the experiments recorded in Table V failed to disclose this fact. The effect at a 10% concentration, however, is small and more than offset by contraction of the "A" stage.

Liquids for Quenching Deep Hardening Steels—Deep hardening steels are used in order that a fully martensitic structure may be obtained with an oil quench and therefore without excessive distortion.

The vapor film stage of cooling, "A," is less important in oil than in water quenching. Actually, the vapor stage may persist longer, Table V, but is not harmful unless exceptionally long because the rate of cooling is faster in this stage with oil than with water, and the critical cooling rate of the steel is properly used with an oil quench. The duration of the vapor stage is longer the lower the boiling point of the oil (Table V) so some bottom limit should be placed on the boiling point of the oil used. Of course the boiling point of oil is a rather indefinite quantity and has to be defined arbitrarily.

Fig. 4—Duration of the vapor film stage of surface cooling during quenching in several liquids.⁶

Table IV
Relation of Brine Density to Salt Concentration

NaCl, %	Lb. Salt per Gal. of Water	Density at 68°F.	Salinometer Reading	Degrees Baumé
0	0.0	1.000	0.0	1.00
5	0.43	1.039	18.9	4.8
10	0.89	1.071	37.8	9.6
15	1.39	1.108	56.6	14.2
20	1.92	1.148	75.6	18.7
25	2.44	1.189	94.5	23.1

The boiling points of the oils listed in Table V are so high that moderate increases in oil temperature have little effect on the duration of vapor film cooling. Consequently, oils, contrary to water solutions, can be used while warm without danger of incomplete hardening and with advantage in some respects. The cooling power of warm oil in the "B" stage is actually higher than that of cold oil. It is

undoubtedly due to lowered viscosity which permits more rapid movement of vapor carrying heat away from the metal surface. A real advantage of using warm quenching oil, however, arises from consideration of residual stresses.

There is danger of cracking deep hardening steels by fast cooling into the hardening transformation as already shown. This transformation usually occurs during cooling in the "C" stage. If then cooling, in this stage, can be slowed down materially, there is less danger of cracking. Referring to Table V, cold oil has an advantage over water in this respect. The cooling rate in the "C" stage of oil is about 1-10 of that in the "B" stage while with water the ratio is about 1-6.5. However, the major advantage of oil is that its temperature can be raised considerably without bad effects, thereby lowering decidedly the cooling rate of the work when approaching the hardening transformation.

Table V

Cooling Rates at Center of $\frac{1}{4}$ in. Dia. Cylinder During Quenching in Still Liquids at 104°F. Showing Variation in Cooling Action with Surface Temperature of Pieces.*

*Cooling rates in "A" stage taken at 1472-1292°F.; in "B" stage at 1022°F.; and in "C" stage at 392°F.

Caution must be exercised in using warm quenching oil. Its temperature should not be so high that it flashes or burns after work is immersed or is dangerous to workmen using it. These considerations are the basis for the rule:

Keep quenching oil warm, preferably between 90 and 140°F.

This rule is particularly important when hardening tool steels which, being high in carbon content, are highly susceptible to cracking. Their hardening transformation, however, occurs at a low temperature, so much is gained by a small increase in bath temperature. If this expedient is insufficient to prevent cracking the work may be removed just before the start of the hardening transformation and cooled in air. Whether or not transformation has started can be determined with a permanent magnet, the work being completely nonmagnetic before transformation if completely hardened by the quench.

So far only generic qualities of oils have been considered. To be specific about the selection of an oil among the numberless compositions available is difficult. The only practical way of identifying oil compositions is by their physical properties and only a few investigators of cooling characteristics have recorded identifying properties, notably those whose data is given in Tables V and VII. Their standard tests are still probably inadequate to assure reproduction of the major properties required in quenching. A list of standardized tests of oils is given in Table VI and is probably sufficiently inclusive to assure duplication of good quenching properties found in a particular oil.

The standard tests are also important with regard to secondary requirements of quenching oils. Low viscosity assures free draining of oil from the work and therefore low oil loss. A high flash and fire point assure a high boiling point and reduce the fire hazard which is increased by keeping the oil warm. Low pour test assures ample viscosity when cold. A low carbon residue suggests stability of properties with continued use and little sludging. The steam emulsion number should be low to assure low water content, water being objectionable because of its vapor film forming tendency and high cooling power. A low saponification number assures that the oil is of mineral base and not subject to organic deterioration of fatty oils

which gives rise to offensive odors. Viscosity index is a valuable property for maintenance of composition.

Tests for these properties are suggested however only as a means for maintaining the composition of an oil found to be satisfactory by experience. Continuity of properties is perhaps the most important requirement for quenching oils. Another is that sludge shall not deposit on cooling coils. Films of salt on the work as when quenching from fused cyanide bath are detrimental to oil. In this case use of a straight mineral oil is indicated.

*Cooling power is measured by the cooling rate of a ½ in. dia. cylinder of 1% C steel when it has cooled to 1328°F. from 1607°F. while in still oil. Values of cooling rate are relative to that for quenching in still water which is 356°F./sec = 1.00.¹⁰

¹These are probably oils with a mineral base and contain 3.3% fatty acid.

²Taken at 95°F.

³Pa. pale neutral oil—viscosity 65 at 100°F. (Saybolt)—flash point 360°F.

⁴Pa. heavy residuum crude oil, steam refined—viscosity 1200 at 100°F. (Saybolt)—flash point 534°F.

Efforts have been made to secure quenching characteristics in water base liquids equivalent to those of oil. This is an admirable objective but so far has been entirely unsuccessful. Oil cooling rates in particular temperature ranges can be secured, but not throughout the whole temperature range of quenching and therein lies the trouble. Scott,¹¹ for example, shows that a mixture of glycerin and water will give a cooling rate in the "B" stage which is the same as that of a popular proprietary quenching oil. The cooling power of this liquid in the "C" stage, how-

ever, is much faster than that of oil, which condition is highly objectionable from the viewpoint of residual stresses. The same objection applies to solutions of ethylene glycol and sodium silicate in water. Also, the duration of the "A" stage in all of these liquids is increased by the presence of water which endangers completeness of hardening.

Emulsions of oils in water also have been used as quenching media. Their characteristics are even worse than those of the solutions just mentioned. The "A" stage cooling is greatly extended and the "C" stage is practically as fast as water. This reversal of the ideal relations between the stages is shown clearly in Table II. Thus there is no obvious prospect of a water containing substitute for oil being developed.

Constitution Diagrams

By J. E. Schoen*

A metal may exist in at least three distinct states: vapor, liquid, or solid. In addition to these three general states, many of the common metals will appear in more than one solid form thus increasing the number to more than three. These states are usually called phases and may be illustrated by a simple substance such as water, the liquid phase of H_2O , steam, the vapor phase, and ice, the solid phase. Each of these phases exists throughout a certain range of temperature, with the solid at the lower end of the temperature scale, followed by the liquid and finally at the higher temperature by the vapor. In the case of ice, when the pressure is atmospheric, it is well known that melting occurs at $32^\circ F$. producing water which in turn boils at $212^\circ F$. forming steam. These temperatures are definite (with constant pressure) and are easily obtained experimentally due to the rather large heat absorptions when either the ice melts or the water vaporizes because during these changes of state the temperature remains constant. In the study of metals the vapor state and the effect of pressure on the temperatures at which these phase changes occur are relatively unimportant and will be disregarded.

However, while the temperature at which a phase change occurs is definite for one metal it can be either lowered or raised by the addition of a second metal or metalloid. Moreover, the freezing process no longer takes place at a constant temperature (except in certain specific instances explained later) and further changes may occur all the way down to room temperature, long after the resulting mixture or alloy has become solid. These changes will vary with increasing amounts of the second metal and if we plot the temperatures at which phase changes take place on a graph whose vertical axis is temperature and whose horizontal axis is concentration or composition and in addition connect these points by smooth lines we produce

Fig. 1d—The cooling of an alloy where crystals of some primary phase solidify first followed by the simultaneous freezing of two phases from the melt.

a diagram called the equilibrium diagram or constitution diagram of the system.

In many alloy systems these changes of state take place rather slowly, particularly in the solid state. Therefore since the diagram must always represent conditions of equilibrium or balance, it follows that the phase relationship is seldom valid for any ordinary heat treating process but is approximated most closely by very slow cooling.

When an alloy is quenched in water or oil, the phases tend to remain in the state indicated by the diagram at the temperature from which they are quenched. If this state is not maintained some transitional state intermediate between this and the normal one at room temperature will be obtained. These transitional states, relatively unstable, are not shown by the equilibrium diagram.

The construction of these diagrams is based primarily on changes in the cooling or heating rates of a series of alloys whose compositions constitute a cross section of the system. These changes are best shown in the accompanying cooling curves.

In Fig. 1a the substance goes through no change of state from 1-2, and the rate of cooling which is extremely rapid at the higher temperature is retarded as the temperature of the material falls; the last few degrees drop requiring a consid-

*Professor and Head, Department of Mechanical Engineering, Marquette University, Milwaukee.

erable period of time as the material approaches the temperature of its surroundings. This type of curve is typical of any substance whether molten or solid so long as the loss of heat is a sensible one only and is unaccompanied by a change of state. A pure metal in cooling from its molten condition to a solid state will produce changes similar to Fig. 1b. The approach 1-2 to the horizontal portion represents the loss of sensible heat of the liquid and the curve from 3-4 represents a similar heat loss of the solid. The isothermal arrest (shown on the curve from 2-3) is caused by the heat evolution of the freezing metal giving up its latent heat of fusion. This cooling curve is typical of not only pure metals but also stable compounds and certain other alloys discussed later.

Fig. 1c and 1d represent simple binary alloys, the former showing the cooling of a solid solution (an alloy in which metals remain dissolved in each other when solid) in freezing from its melt and the latter an alloy where crystals of some primary phase solidify first followed by the simultaneous freezing of two phases from the melt along the horizontal portion 3-4. It will be noted that the solid solution did not cause the temperature to remain constant during its formation but rather that the change of liquid to solid took place over a range of temperature. This distinction clearly separates this group from the pure metals or compounds of Fig. 1b and also from the more insoluble metals shown in Fig. 1d. In Fig. 1d, for a binary system, when two solid phases form simultaneously from a melt as in a eutectic reaction (as seen later); cooling curves always manifest these horizontal portions.

Alloys which on solidification remain partially or completely soluble frequently show a decreased solubility of the constituent parts when allowed to cool to room temperatures. These further changes of state are usually accompanied by heat evolutions which will again affect the cooling curve, causing its smooth downward path to be disrupted by further arrests. When these heat reactions are small—and this is usually true of solid changes occurring at temperatures not far above room temperature—the change of direction in cooling curves escapes detection by ordinary means and other methods of inspection must be resorted to in order to reveal the complete story of the constitution diagram. These methods, approximately in their order of use, are: 1. Micrographic analysis; 2. X-ray diffraction; 3. dilatometric measurements; and 4. miscellaneous.

Classification of Systems—An inspection of the equilibrium diagrams given in this Handbook reveals that the changes taking place are often varied and complex. For example, alloys of copper and zinc or iron and carbon may exist when solid as a number of solid solutions or intermetallic compounds, and these states are not usually formed directly from the melt but follow after a series of intermediate steps or changes. In order therefore that these complex combinations may be clearly understood it is necessary to break them down into simple types which can be easily analyzed.

The usual method of classifying these simple binary types follows:

1. Alloys soluble in the molten state:
 - a. Soluble when solid
 - b. Insoluble when solid
 - c. Partially soluble when solid

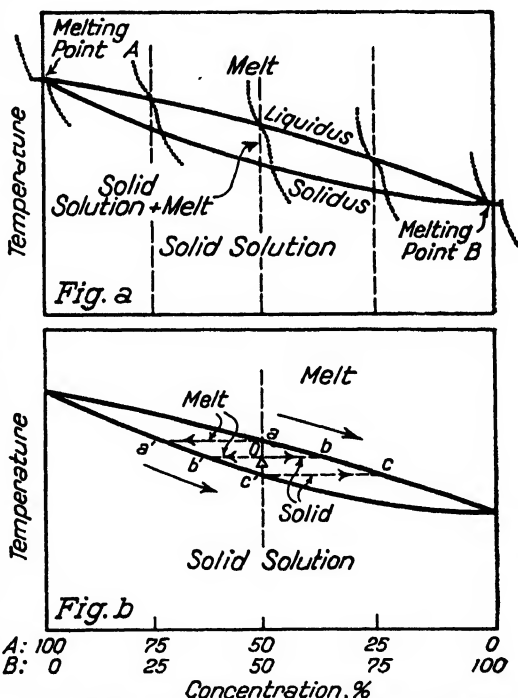

Fig. 2a—Illustration of two metals that form a solid solution.

Fig. 2b—Solidification of a solid solution alloy.

2. Alloys partially soluble in the molten state:
 - a. Insoluble when solid
 - b. Partially soluble when solid
3. Changes in solid alloys which are partially or wholly soluble on solidification.

Solid Solution Alloys—When two metals combine in this form the resulting alloy diagram may assume, as one possibility, a shape similar to Fig. 2a. The upper line connecting the initial freezing points of the several alloys slopes away gradually from the higher melting point metal A to metal B and is called the "liquidus" line since everything above it is in a liquid or molten condition. The lower line completing the envelope connects the end points of the freezing process and is known as the "solidus" line. Below it the alloys are completely solid.

In order that the mechanism of crystallization may be more clearly understood, it is desirable at this point to introduce several of the simple rules which outline the behavior of alloys during solidification.

Rule I, Qualitative Equilibrium—At any temperature in a heterogeneous field (containing either solid and melt or two different solid phases) the nature of the phases in equilibrium at some temperature can be determined by the intersections of the temperature horizontal with the conjugate boundaries to the field.

In Fig. 2a the conjugate boundaries to the solid and melt field are obviously the "solidus" and "liquidus" lines. Fig. 2b shows that for 50% alloy at temperature a the first solid solution crystals to form will be rich in metal A and have a composition of a' while the melt from which they crystallize has the original composition a. As the cooling progresses the average concentration of the solid and melt correspond to points b' and b respectively. This must follow since the initial solid solution, being rich in metal A, will deprive the residual melt of this metal thus increasing its B concentration and forcing it in the direction indicated. The end point of the freezing cycle will occur at temperature c' and here it is noted that the average composition of the solid is the same as the original melt (50% A, 50% B) while the last traces of melt in equilibrium with this solid have a composition of c.

Rule II, Quantitative Analysis—The amounts of the two phases in equilibrium at any temperature in a heterogeneous field may be determined by the well known "lever principle" of mechanics applied here as follows:

Assume that the intersection of the alloy composition line with the desired temperature horizontal acts as a fulcrum, the quantities of the two phases are then inversely proportional to the intercepts thus created on this temperature horizontal which extends to the conjugate boundaries of the field. In explanation of this refer to the 50% A alloy of Fig. 2b and suppose the temperature to be that at a, where freezing is about to begin. At this point the fulcrum is at a, there being no intercept to the right we have as yet no solid but all melt and 100% of the temperature horizontal lies to the left of the fulcrum. When cooling has progressed to temperature b, the fulcrum is at point o, and the amount of solid present is proportional to intercept o.b to the right of the concentration vertical while the quantity of remaining melt is proportional to the intercept ob' to the left of this vertical line. The entire length of the temperature line represents 100% of the alloy present. In a similar manner at temperature c the last melt has disappeared, and the whole intercept is to the right of the fulcrum, indicating that the alloy has now solidified completely.

The Phase Rule—Willard Gibbs in the latter part of the nineteenth century developed a relationship between the number of phases, the components and the degrees of freedom of a system, which has proven extremely useful as a guide in constructing alloy diagrams. This rule based on thermodynamic concepts and applied to metals in equilibrium may be stated mathematically as follows:

$$F = C + 1 - P$$

where

F = degrees of freedom

C = number of components

P = number of phases

Degrees of Freedom—The number of independent variables (either temperature or concentration of the phases) which may be altered without causing the disappearance of any phase, or the formation of a new phase.

Components—In alloy systems these are obviously the metals or their compounds and, for a given system, there should be chosen as components the smallest number of independently variable constituents by means of which the composition of each phase can be expressed.

Phases—Homogeneous, physically distinct matter, such as the physical states

liquid or solid with the latter having several possible forms, namely, pure metals, compounds and solid solutions.

As an illustration of the application of this rule, consider the crystallization of the 50% A alloy previously discussed. When the mass is at a temperature above the liquidus line the alloy is a homogeneous melt of A and B, resulting in but one phase in this two-component system (metal A and metal B). Inserting these values in the phase rule, ($F = 2 + 1 - 1 = 2$), the system has two degrees of freedom which implies that both temperature and concentration may be varied within limits without destroying or changing the equilibrium of the system. Another interpretation of this result is that the degrees of freedom also represent the number of variable factors which must be arbitrarily set before the state of the alloy can be determined. When both temperature and concentration vary the system is said to be *bivariant*.

On cooling this alloy to temperature *b*, Fig. 2b, two phases are present, one solid *b'* and one melt at *b*. The system is then *monovariant* (1 degree of freedom) since $F = 2 + 1 - 2 = 1$. If now either the temperature or the concentration of only one of the phases be set, the remaining variable factors immediately follow and the condition of equilibrium is completely determined. Hence in such a binary system it is possible to have two phases such as solid and melt present over a range of temperature and freezing need not occur isothermally as in pure metals.

To make this clear suppose the phase rule be applied to a pure metal while freezing. Obviously two phases are present (solid and melt) and this system is of one component. The degrees of freedom are now represented by $F = 1 + 1 - 2 = 0$ and the system is said to be *invariant*. From this it follows that the temperature must remain constant so long as the solid and melt co-exist and this phenomenon is of course well known to all.

Thus far it has been shown that when solidification occurs in the solid solution type alloys Fig. 2a the concentration of the first particles of solid will be considerably richer in metal A than the melt and also the last melt will be correspondingly richer in metal B. This produces solid crystals which are partially heterogeneous in that the nuclei are rich in one metal whereas the outer surfaces which formed last are rich in the other metal. On slow cooling from the "solidus" line, diffusion or equalization takes place and—given sufficient time at elevated temperature—will be complete at room temperature. The structure will then appear microscopically as a single phase, similar to a pure metal. The alloys of copper-nickel or gold-silver are completely soluble both in the liquid and solid states and the resulting constitution diagrams are similar to the type just discussed (see pages 1353 and 1503).

In addition to the type just described, two other alloy diagrams, showing complete solubility (miscibility) in the solid state, are possible. The first of these, in which the "liquidus" and "solidus" are both depressed, is shown in Fig. 3a and at the minimum temperature these lines become tangent. The cooling curve at this point is similar to that of a pure metal. In other respects the path of crystallization of alloys in this series will follow through precisely the same steps as that of the type just discussed.

Fig. 3b shows a type of solid solubility resulting from a maximum tangent point of both "liquidus" and "solidus" lines. No important binary metal groups are known to follow this behavior but there are several nonmetallic combinations that do. Of the more complex binary systems such as copper-aluminum (page 1342) it will be noted that in the formation of the beta solid solution a maximum occurs at 1047°C. while the system of copper and beryllium (page 1344) contains a minimum temperature in the field of precipitation of its beta solid solution.

Alloys Soluble in the Melt but Insoluble when Solid—These alloys can be divided into three subgroups: (a) Simple eutectic; (b) simple eutectic and stable intermetallic compound; (c) peritectic types.

(a) *Simple Eutectic*—When two metals are insoluble in each other in the solid state, the addition of one to the other will usually cause the freezing temperature of the melt to be lowered (Fig. 4). The intersection of the "liquidus" lines *ae* and *de* at *e* produces an alloy of the lowest freezing point in the series and is called the *eutectic* of the system. The location of this eutectic is specific for a definite combination of metals but may be located anywhere from pure A to pure B throughout the various alloys. A practical example of this alloy diagram is the zinc-tin system (page 1756).

Path of Crystallization—Alloy I (Fig. 4) rich in A will on cooling from a temperature of *x* lose sensible heat until temperature *y* is reached. At this point the first particle of solid appears and by the insertion of the temperature horizontal.

Rule I, this solid is found to be pure A. Fig. 4 shows that the boundaries to the heterogeneous field of solid A plus melt are the solidus line *ab* and the liquidus line *ae*.

A break in the smooth path of the cooling curve will be noticed due to the evolution of heat by the solid A being formed. It follows now that if pure A separates from the melt, this melt becomes increasingly richer in B and with falling temperature, its concentration will vary from its initial condition *y* along the liq-

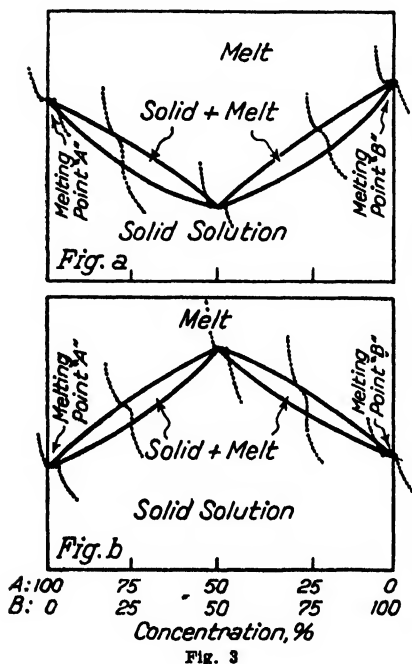

Fig. 3a—Alloy diagram showing complete miscibility in the solid state with the liquidus and solidus depressed.

Fig. 3b—Type of solid solubility resulting from a maximum tangent point of both the liquidus and solidus lines.

Fig. 4—Diagram for two metals that are insoluble in each other in the solid state.

uidus line *ae* until the eutectic point *e* is reached. Meanwhile the solid A crystals have grown in size and number and at the eutectic temperature *bze* equilibrium is established between primary A crystals just formed and a melt whose concentration is *e*. The melt now freezes, depositing simultaneously the remaining A and B as separate and distinct phases. The temperature remains constant while eutectic melt is present. The resulting eutectic microstructure usually shows finely divided alternate lamellae of A and B. Applying the phase rule to this part of the system we find present three phases, two solids, pure A and pure B, and the eutectic melt *e*. In this binary system the eutectic freezing is therefore an invariant condition since $F = 2 + 1 - 3 = 0$. This simply means that whenever both solid A and B are present with the melt *e* the temperature must remain constant and that only one certain temperature will satisfy. This accounts for the horizontal "solidus" *bec* or base to the "liquidus" curves *aed*. The microstructure of the completely solidified alloy I will consist of primary A crystals in a matrix of eutectic (A + B).

Alloy II—For an alloy whose concentration is that of the eutectic *e* the cooling of the melt will occur from *s* to *e* without the formation of any solid. At the eutectic temperature *bec* the solidification of pure A and pure B again takes place simultaneously at constant temperature. The resulting solid microstructure will be entirely eutectic (usually a finely divided matrix of A and B).

Alloy III—When the alloy has a composition between *e* and *c* it will on cooling below the liquidus line (*d e*) precipitate primary B crystals thus forcing the composition of the remaining melt to the left. This process continues to the eutectic temperature *elc* where the formation of the solid eutectic (A + B) occurs. The final microstructure will consist of primary B crystals imbedded in a matrix of eutectic (A + B).

(b) *Eutectic Alloys with Stable Intermetallic Compound*—Many binary alloys contain one or more intermetallic compounds but are otherwise completely insoluble when solid. Fig. 5 is typical of this series, containing one compound A_xB_y and two separate eutectics at e_1 and e_2 . The cooling of the intermetallic compound A_xB_y is similar to a pure metal and its melting point is at a maximum point c in the liquidus line e_1ce_2 . The simplest method of analyzing these alloys is to break down the composite diagram into simple eutectic types as shown to the left and right of the principal figure. It can then be assumed that A_xB_y is a separate component and the two binary figures are subject to the same changes previously described for eutectic types.

Briefly, alloys whose composition fall between b and e_1 , have an excess of A over and above the eutectic e_1 . The resulting solid will contain primary A in a ground mass of eutectic e_1 ($A + A_xB_y$). To the right of this eutectic, the compound will precipitate out first and the final microstructure will contain it as a primary phase surrounded also by eutectic e_1 . Compositions to the right of the A_xB_y vertical will yield structures as indicated in the diagram with a matrix or background of eutectic e_2 ($A_xB_y + B$).

(c) *Peritectic Systems*—When a binary compound is unstable with a melt of its own composition the resulting diagram takes on a new form as in Fig. 6. The figure itself will, in part, explain the reason for the many headings under which this system is discussed by the profession. In addition to the title given, it is variously labeled "transition type," "unstable compound" and "hidden maximum," all of which tend to be descriptive of the unusual change occurring at the temperature bce' .

An alloy of composition I will on cooling to temperature t remain in a soluble molten state. At this temperature nuclei of solid A come into equilibrium with the melt, thus forcing it to the right toward point e' (peritectic point) as cooling proceeds, the precipitation of solid A continues. At the peritectic temperature bce' the equilibrium in the alloy is between a predominant amount of solid A and the remaining melt whose composition is e' . It is at this point that the unstable compound A_xB_y enters the picture as the third phase, creating an invariant condition, with the resultant temperature arrest in the cooling curve. Obviously the compound A_xB_y cannot wholly form from a melt whose composition lies to the right at e' and is therefore much richer in metal B . To compensate for this, some of the metal A reacts with the melt, as the compound forms, maintaining its concentration at e' until its disappearance. The final microstructure of the mass must be solid A crystals formed prior to the transition surrounded by the compound A_xB_y .

For alloy II , the initial reaction will be like that of alloy I . Cooling from temperature m to n will permit the freezing of primary A but to a much lesser extent than before. At the transition temperature the equilibrium will again be between solid A , melt e' and the compound A_xB_y . The reaction continues as before with the resorption of primary A into the melt while A_xB_y freezes out, but not for long, since the quantity of excess A is not large and it soon vanishes completely. With the disappearance of the solid A phase the temperature no longer remains constant and the concentration of the melt gradually slides toward the eutectic e while the A rich intermetallic compound A_xB_y forms. Freezing ends at the eutectic temperature def

Fig. 5—Typical diagram of binary alloys containing one or more intermetallic compounds and are insoluble when solid.

when the small amount of residual melt simultaneously precipitates A_xB_y and B in a typical eutectic arrangement.

When the composition of the melt is exactly that of the compound A_xB_y , the two phases primary A and melt e' are correctly proportioned and disappear simultaneously at the transition temperature.

Alloys Soluble in the Melt but Partially Soluble when Solid—Most alloy systems of commercial importance fall in this group although frequently the degree of solid solubility is only slight. Solid solutions are customarily labeled with letters of the Greek alphabet to distinguish them from pure metals and compounds (see page 67 for Greek alphabet). The number of possible fundamental types of diagrams is about the same here as it was in the previous series and their analysis will follow the same order.

Fig. 6—Diagram of binary compound unstable with a melt of its own composition.

Simple Eutectic—An alloy rich in metal A and having a composition similar to I in Fig. 7 will on freezing first deposit as nuclei, solid solution crystals whose composition tends to be almost pure A. As these crystal centers grow in size by the further deposition of solid metal, the concentration of the mass becomes increasingly richer in metal B. The liquid concentration follows along the heavy portion of the liquidus line ae while the average solid concentration is indicated by the heavy portion of the solidus line ab . Solidification is complete at the temperature corresponding to the intersection of the concentration vertical with the solidus line ab and no further change occurs in cooling to room temperature. It is evident that the portions of the diagram to the left of b or to the right of c trace the same path of crystallization

Fig. 7—Diagram of simple eutectic showing the freezing of solid solution crystals whose composition is rich in one of the metals.

as the solid solution systems discussed in the beginning.

There is this difference, however, the A rich solid solution α is saturated with metal B when the composition of the alloy is b and in a like manner the B rich solid solution β becomes saturated with metal A when the amount of this phase corresponds to composition c . The predominant metal in either case is considered to be the solvent and when the compositions tend to approach the 100% A or B verticals the solid solutions thus formed are termed unsaturated. These unsaturated solid solutions may of course become saturated at lower temperatures and precipitation of the second phase then occurs. For example, alloy II which is unsaturated with respect to metal B will, after solidification (at I), cool as a homogeneous solid solution to a temperature m (at the intersection of the concentration vertical with

the solid solubility line bf) where a second solid phase precipitates from this homogeneous α . The nature of this phase can be determined by applying Rule I—drawing the temperature horizontal at m it is found to intersect the solid solubility line cg on the right and β solid solution of n concentration is the precipitate phase.

Fig. 8—Diagram of peritectic type.

sect the solid solubility line cg and from which the α phase will separate. For the portion of the diagram lying between compositions b and c the reaction is of a typical eutectic form. Alloy III for example will contain primary crystals of β surrounded by a lacy network matrix of eutectic structure. There are many simple actual alloy systems on this order such as $Sb-Pb$, $Sn-Pb$, $Bi-Pb$, $Cu-Ag$, and others.

Peritectic Type—Comparing this type diagram, Fig. 8, with the previous peritectic equilibrium for insoluble conditions (Fig. 6), it is clear that the melt traces precisely the same path in both instances and the only distinction occurs in the solid phases which are now the two solid solutions α and β as compared with pure A and the compound A_2B in the former case.

Commercially common alloys which behave in a fashion comparable to simple alloys already considered are not difficult to find. There are peculiar combinations of several simple systems or perhaps a repetition of the same. A case in point is the tin-antimony constitution diagram on page 1699.

Partial Solubility of the Melt with Insoluble Solid—When two metals are partially soluble in the molten state the liquidus line of the equilibrium diagram now has superimposed on it the heterogeneous two melt field as shown in Fig. 9. The alloy system chosen to illustrate this type of reaction is of a simple insoluble eutectic

Fig. 9—Diagram of partial solubility of the melt with insoluble solid.

type. An inspection of the final phases and microstructures indicates that the breakdown of the single melt into two melts does not affect the final result. Alloy I will on cooling through the liquidus line *ah* freeze out primary A crystals to the

Fig. 10—Variation of partial solubility of the melt with insoluble solids.

temperature *bhg*. On arriving at this temperature the melt will have a composition of *h* and continued precipitation of solid A from this melt will cause the formation of the second melt of composition *g*. This may be stated in equation form as follows:

This three phase reaction, sometimes referred to as a "monotectic" reaction, takes place isothermally and further drop in temperature does not occur until the melt *h* disappears. The solidification process then is the same as for the simple eutectic type in that primary A continues to form, forcing the melt ultimately to the eutectic concentration *e*.

Solidification of alloy II differs from alloy I only in its initial stages. Cooling below temperature *x* above the two melt field, the single melt separates into con-

jugate melts which at temperature *j* will be of composition *y* and *y'* and at *k*, *z* and *z'* respectively. At temperature *bhg* the two melts will have the compositions of *h* and *g*. The cooling reactions from this point are now the same as before with melt *h* precipitating some solid A.

The dome shaped field limiting the temperature and concentrations at which two melts may exist is not always well defined in its upper regions. This is due to the small thermal changes which occur in the formation of the conjugate melts. The isothermal reaction is, however, always clearly defined. Copper and lead (page 1349) or zinc and lead (page 1748) both show partial solubility in the molten state.

Another variation of this type of equilibrium, where the melt is partially soluble, is illustrated in Fig. 10. The dome shaped two melt field is now superposed directly over an intermetallic compound. Alloys of this system having a composition between *h* and *c* will on cooling to a temperature of *hcg* consist of melt *h* and melt *g* with an excess of the former. The compound A_xB_y , then freezes isothermally from a combination of the two melts and the reaction is complete when melt *g* disappears.

For alloys having a composition between *c* and *g* the reactions are the same except that melt *h*, which is now present to a lesser extent, will disappear first, following which the compound A_xB_y continues to freeze in the usual manner. The three phase isothermal reaction at temperature *hcg* is sometimes termed a "syntectic" reaction and the diagram is named accordingly.

Fig. 11—Diagram for an alloy partially soluble in both the liquid and solid states.

Partially Soluble in Both Liquid and Solid States—By slightly modifying the diagram of Fig. 9 as in Fig. 11 partial solubility in the solid state is indicated. If in the above analysis the A rich solid solution α is substituted for the metal A and the B rich solid solution β for the metal B we can trace through precisely the same steps as before. The system of tin and phosphorus (page 1705) is of this type.

In a similar manner the alloy system of Fig. 10 may be altered by having not only primary solid solutions α and β at the terminal points but also by replacing the intermetallic compound A_2B_3 by an intermediate phase showing extended solubility. This intermediate phase or solid solution which could be labeled γ will then result from the combination of the two melts b and g and replaces A_2B_3 on the diagram.

Complete Insolubility in Both Liquid and Solid States—The last of the liquid-solid transitions, sometimes presented, is that of a binary system which is insoluble under all conditions. The two metals act independently of each other and solidify at their respective freezing points regardless of composition. The diagram (Fig. 12) consists of two parallel horizontal lines and the resultant mass likewise consists of two distinct layers. Fe-Ag resembles this type.

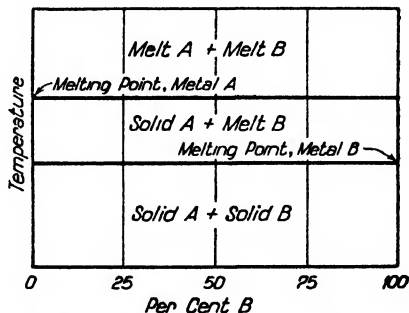

Fig. 12—Diagram showing insolubility in both the liquid and solid states.

Transformations in the Solid State—

The discussion just completed treats entirely with the transformation of liquids or melts into solids. The study of the decomposition of solid alloys, which exist in the form of solid solutions on freezing is of equal importance. These solid solutions may transform into compounds, secondary solid solutions, or the simple metals much in the same fashion as the reactions previously described and it is the control of the rate of these decompositions which makes it possible to vary the ultimate physical properties of alloys.

The first factor of importance in the study of solids deals with the change which some pure metals undergo on cooling, known as *polymorphism* and defined as that property of a metal which causes it to appear in more than one solid crystalline form. These various forms of a metal are labeled with letters of the Greek alphabet (like solid solutions) and may be distinguished not only by the arrangement of the atoms in their crystal lattices but also by the difference in some of the physical properties in each instance. For example pure iron appears on freezing as delta, later as gamma and finally at ordinary temperature as alpha iron.

Outwardly, the polymorphic modifications of iron appear much the same but with some substances this property too may vary greatly as in the case of carbon which may exist as a diamond, graphite or temper carbon. Likewise ordinary white tin on cooling to subzero temperatures may be converted to a gray, powdery state.

Complete Solid Solutions of Two Polymorphic Metals—Certain binary combinations of metals which are miscible when solid will, because of polymorphic modification of one or both constituents, cause secondary changes indicated by Fig. 13a, b, c.

The first of these, Fig. 13a, may be produced by two metals A and B when each exists in two polymorphic states, α and β , and also when because of the similarity of the two metals in crystalline form, and atomic radius, they tend to remain in solution as a solid. The essence of the second transformation from α to β solid solution is the same as that of the liquid to solid change occurring above it. The α solid solution will on cooling remain homogeneous until the upper transformation or upper critical line acb is reached. At this temperature are born the first crystals of the β solid solution whose concentration can be obtained by drawing temperature horizontals in the $\alpha + \beta$ field and the transformation from α to β continues until the lower critical adb is reached. The change is now complete and further cooling to room temperature will leave this β phase in a homogeneous state.

Loop Type Diagrams—The envelope abcd enclosing the $\alpha + \beta$ field is commonly called a loop. In both Fig. 13a and 13b this loop is closed whereas in the third type 13c it remains open. The latter two result when a metal such as B goes through no polymorphic changes, though it is possible that in Fig. 13c the $\alpha + \beta$

Fig. 13a, b, and c—Typical diagrams for complete solid solutions of two polymorphic metals.

field may be closed at extremely low temperatures where a second modification of either A or B may exist.

The alloys of iron-tungsten or iron-chromium among others exhibit a characteristic closed loop similar to Fig. 13b where the γ form of iron dissolves either tungsten or chromium to a limited extent. In this instance it is possible for an alloy whose composition lies in this range to change, on cooling, from the α solid solution to the second type and later back to the α form. It is also possible, when cooling drastically from within the loop, to maintain the intermediate state. Of the third type, Fig. 13c, iron and nickel offer a good example and it is possible to obtain at ordinary temperatures either the α form, a mixture of α and β (β in Fig. 13c but γ in the Fe-Ni system) or the β form alone. The mechanism of the change is similar in each case.

Order-Disorder—Another type of transformation in the solid state is the so-called order-disorder change which is described in the article on the Crystal Structure of Metals and Alloys in this Handbook.

Solid Solution Decomposition Resulting in Partial Solubility—When solid solutions become less soluble they may also go through a eutectic-like reaction in the solid state producing ultimately partially or wholly insoluble aggregates.

The partially soluble state is illustrated by Fig. 14a and the eutectic type of reaction, now called *eutectoid* occurs at the temperature *bec*. The path of crystallization for an alloy to the left of the eutectoid *e* and between *b* and *e* can be traced as follows:

The primary solid solution γ on cooling through the transition *ae* at *m* will precipitate the secondary solid solution α having a composition *n*. This α phase, commonly called the proeutectoid constituent, will have a composition varying to *b* at the eutectoid temperature *bec*. Meanwhile the γ solid solution will become richer in metal B and at this temperature its concentration is that of point *e*. A simultaneous deposition of the two phases α_e and β_e solid solutions from the residual γ_e then produces the characteristically finely divided matrix of a eutectoid reaction. The microstructure of the "eutectoid" is usually that of alternate lamella of α and β or

Fig. 14a—Diagram for solid solution decomposition resulting in partial solubility.

spheroids of one in the other, requiring rather high magnification to bring about their resolution. Its particle size is much smaller than that of corresponding eutectic structures.

A composition exactly at *e* will, of course, result entirely in a eutectoid structure while alloys to the right between *e* and *c* will be made up of proeutectoid β imbedded in the eutectoid background.

Decomposition of Solid Solutions Resulting in Insolubility—When the solid solution breaks down into complete insolubility and is of the eutectoid type its form may be depicted by Fig. 14b. In this case the proeutectoid constituent is either pure A or pure B while the eutectoid contains both. The transformation is similar to the previous type.

Decomposition of Solid Solutions Resulting in a Peritectoid Reaction—The last class of solid solution decomposition is that of the peritectic or resorption type and is called peritectoid or metaectectic. This form of equilibrium, and this is equally true of all of the diagrams previously given, may have many variations. Fig. 15a, b, c show three types of diagrams. The mechanism of the transformations of solid alloys of this type is similar to the liquid-solid reactions of systems having the same form of equilibrium diagram. Thus Fig. 15b shows how the β solid solution like the melt of Fig. 6 becomes ultimately

completely insoluble and consists for alloy I of a mixture of A and the compound A_2B_3 (the product of the resorption of primary A with the β phase) while alloy II carries on below this transition temperature and does not break down completely until the eutectoid temperature *def* is reached. The end microstructure for this alloy, as indicated in the figure, will be made up of excess compound A_2B_3 imbedded in a matrix of eutectoid ($A_2B_3 + B$).

The only purpose in presenting Fig. 15c is to show how frequently the dotted solid solubility lines *cm* and *dn* shift to one side and become joined as at the point *b* where in some instances a polymorphic phase change occurs. This is particularly true of the alloys of iron in the high temperature field and for compositions rich in iron. The phases are labeled as in the iron-carbon system. The δ solid solution on cooling through the upper transformation line *cb* will decompose to the γ solid solution and the transition is complete at the lower transformation line *bd*. Between these two conjugate boundaries δ and γ co-exist.

Summary—Summarizing the previous discussion on the constitution diagrams of binary systems, certain simple rules may be stated which should facilitate the reading of these graphic illustrations of metallic equilibrium.

1. Under inclined liquidus lines two phases exist, one of which is the melt.
2. Under inclined upper solid transformations two solid phases exist one of which is a solid solution.
3. Under inclined "solidus" lines or inclined lower solid transformations a single solid phase exists (solid solution).
4. Along horizontal lines three phases exist.
5. Two of these phases are indicated by the compositions at the ends of the horizontal line.
6. The third phase depends on the shape and nomenclature of the diagram as shown in Fig. 16.
7. Stable intermetallic compounds usually occur under maximums of the liquidus lines and appear as a vertical or vertical range extending from the liquidus down to room temperature.
8. The drawing of temperature horizontals in heterogeneous (two phase) fields yields the compositions of the phases in equilibrium at that temperature.
9. The reactions which take place on cooling will also occur on heating but in a reversed order and for solid transformations at slightly higher temperatures.

Fig. 14b—Diagram for decomposition of solid solutions resulting in insolubility.

10. Slow cooling is essential if normal equilibrium reactions are to occur.

11. Rapid cooling tends to preserve the state of the alloy in its initial condition which existed immediately prior to cooling.

12. Intermediate rates of cooling may produce unusual final aggregates due to the particle size of the precipitated phase and the obstructive effect caused thereby.

Constitution of Binary Alloys of Iron and Certain Other Elements

By R. M. Parke*

Of the various binary systems containing the element iron as one component, work on about 55 has been reported in the literature, while 30 have been investigated sufficiently to permit the construction of at least a partial equilibrium diagram. Several systems of the latter group have been separately treated in other sections of this handbook. The present article summarizes the more important information that exists for some 39 of the rarer iron binary systems. For a more complete presentation of the available information on these systems, the reader is referred especially to the excellent works of Hansen ("Der Aufbau der Zweistofflegierungen" published by Julius Springer, Berlin, 1936), Jänecke ("Kurzgefasstes Handbuch aller Legierungen", published by Otto Spamer, Leipzig, 1937) and Vogel ("Handbuch der Metall Physik, II—Die heterogenen Gleichgewichte" edited by G. Masing, published by Akademische Verlagsgesellschaft, Leipzig, 1937), each of which was extensively consulted here.

Antimony-Iron—Antimony-iron alloys have been studied by Laborde¹ and Maey², by Kurnakow and Konstantinow³, Wever⁴, Hagg⁵, and Vogel and Dannöhl⁶. From these researches it appears that the Sb-Fe system has a closed gamma field, two compounds⁷ occur (Fe₃Sb, FeSb₂), and the iron-rich solid solution⁸ will hold up to 7%† Sb. The limit of the gamma loop has been tentatively estimated by Vogel and Dannöhl⁶ at slightly over 2% Sb.

Argon-Iron—Argon¹ and helium do not diffuse through iron so that it may be assumed that these gases are not soluble in iron. According to Sieverts and Bergner² electrolytic iron does not absorb any inert gas at 1200°, 1400°, or 1500°C.

Arsenic-Iron—The constitution of As-Fe alloys has been studied by Friedrich¹, Oberhoffer and Gallaschik², Weyer³ and Hagg⁴. The eutectic occurs at about 70% Fe and 830°C. between the compound Fe₃As and the iron-rich (92% Fe) solid solution. From Hagg's work it appears that the solubility of As in Fe decreases with decreasing temperature. Wever determined that a closed gamma field exists. An additional compound (FeAs) was identified by Hagg.

Hansen⁵ has presented a partial diagram based on the work of the above investigators and others. This diagram places the limit of the gamma loop provisionally at about 1.5% As since the existence of the gamma loop is not in agreement with the work of Oberhoffer and Gallaschik².

*Climax Molybdenum Co. of Michigan, Detroit.

Prepared for the Subcommittee on Alloying Elements.

The membership of the subcommittee was as follows: Jerome Strauss, chairman; Walter Crafts, J. W. Sands, Harry Knowlton, L. L. Farrell, A. J. Herzig, Emil Janitzky, C. H. Herty, Jr. and E. C. Bain.

†Unless otherwise stated compositions are given in weight per cent.

Barium-Iron—Barium, lithium, sodium, potassium, rubidium, caesium, magnesium, calcium and strontium¹ are insoluble in solid iron. Iron is not dissolved by the foregoing liquid metals, and although their solubility in liquid iron is not known, (the boiling points of the metals are all below the melting point of iron) the possibility of the formation of alloys is considered improbable.

¹M. Hansen, *Der Aufbau der Zweistofflegierungen*, Julius Springer, Berlin, 1936 p. 675.

Beryllium-Iron—The liquidus and solidus lines of the iron side of the Fe-Be diagram have been determined by Oesterheld¹. He estimated that iron could dissolve at least 6.5% Be at 1155°C., the eutectic temperature. The eutectic contained 9% Be. Oesterheld believed that the solubility of Be in Fe decreased with temperature and this is supported by precipitation hardening experiments of Masing² and Kroll³. Oesterheld tentatively identified a compound of the formula Be_3Fe , which was confirmed by Misch⁴, who determined that Be_3Fe has a hexagonal lattice similar to MgZn_2 . Misch also investigated the compound Be_2Fe (55.32% Fe) which he stated has a Cu_2Mg structure similar to CuBe_2 .

Wever and Müller⁵ found that the Fe-Be system has a closed gamma loop and that the alpha-gamma transformation disappears at 0.45% Be.

Hansen⁶ and Jänecke⁷ published a partial equilibrium diagram (79-100% Fe).

Bismuth-Iron—According to Isaac and Tammann¹, Bi and Fe are practically insoluble in each other in the molten state, and this has been confirmed by Hagg². Using a magnetic method Tammann and Oelsen³ determined that 2×10^{-4} to $4 \times 10^{-4}\%$ Fe was dissolved in Fe-Bi alloys heated at 400 and 1600°C. under a hydrogen atmosphere.

Boron-Iron—This system has been studied by Tschischewski and Herdt¹, Hannesen², Vogel and Tammann³ and Wever and Müller⁴. On the basis of these researches Hansen⁵ has constructed a partial diagram. A eutectic between the gamma phase and the compound Fe_2B occurs at 3.8% B and 1174°C. The maximum solubility of B in alpha iron is 0.15% at 915°C., the solubility decreasing at lower temperatures. The maximum solubility of B in gamma iron is 0.10% at 915°C., while the maximum solubility in delta iron is 0.15% at 1381°C. Wever and Müller⁴,⁶ determined that the compound Fe_2B has a body-centered tetragonal lattice with 4 Fe_2B groups in the unit cell. Bjurström and Arnfelt⁷ verified the structure of Fe_2B and also determined that the monoboride FeB has a rhombic structure with 4 FeB groups to the unit cell. Wever and Müller⁴ concluded that B slightly raises the alpha-gamma transformation of iron.

Cadmium-Iron—Cadmium is insoluble in solid iron. Tammann and Oelsen¹ determined the solubility of iron in molten cadmium in the range 400-700°C. to be 3×10^{-4} to $2 \times 10^{-4}\%$ Fe. According to Daniels² a compound, Cd_3Fe , exists.

Caesium-Iron—See barium-iron

Calcium-Iron—See barium-iron

Cerium-Iron—The Ce-Fe equilibrium diagram has been completely determined by Vogel¹. Two compounds, $CeFe_2$ and Ce_2Fe_3 , were identified. The eutectic occurs at 4.5% Fe and 640°C. The maximum solubility of Ce in gamma Fe is 15% Ce at 1090°C., while in alpha iron the maximum solubility is tentatively placed at 12% Ce. Ce slightly raises the temperature of the alpha-gamma transformation. The pyrophoric property of Fe-Ce alloys is greatest at 30% Fe according to Auer v. Welsbach², but see also Vogel¹ for an explanation of this property. See Hansen³ or Jänecke⁴ for the diagram of this system.

Cobalt-Iron—Iron and cobalt form a continuous series of solid solutions. Iron-cobalt alloys solidify over a very narrow temperature range (5-10°C.)¹, with a minimum of 1477°C. between 30% and 40% Fe. Cobalt raises the gamma-delta transformation of iron. This metal also raises the alpha-gamma transformation continuously up to about 45% Co (975°C.) when further additions lower the temperature of the transformation until at approximately 78% Co gamma iron is stable at room temperature. Iron drastically lowers the transformation of the hexagonal close packed epsilon cobalt phase to the face-centered cubic gamma phase.

Based on the work of Guertler and Tammann¹, Ruer and Kaneko², Kase³, Masumoto⁴, Grenet⁵, Kussmann, Scharnow and Schulze⁶, Andrews⁷, Ellis⁸, Osawa⁹ and others, Hansen¹⁰ and Jänecke¹¹ have constructed a complete equilibrium diagram of cobalt-iron alloys. Recently Andrew and Nicholson¹² confirmed the essential points of the diagram except that they believe that there is a wide alpha + gamma region extending from 74-82% cobalt.

Gold-Iron—From the work of Isaac and Tammann¹, it has been determined that iron and gold are miscible in all proportions in the liquid state. There is a limited gamma field. According to Hansen², Wever believes the compound AuFe₃ exists. At low temperatures there are probably three phases, depending on the composition, namely: iron-rich (alpha) solid solution, compound and gold-rich solid solution. At higher temperatures, alpha, of course, changes to gamma. There is some disagreement as to the phase boundaries, but the following X-ray data on the solubility of Fe in Au, from Jette, Bruner and Foote³, are probably reliable:

Temperature, °C.	% Fe
300	3.5
450	6.9
600	12.5
724	17.2

With somewhat less accuracy these investigators determined that alpha iron will dissolve 2.05% Au at 724°C. and 0.6% Au at 600°C.

Helium-Iron—See Argon-iron

Hydrogen-Iron—The principal work on this system has been the determination of the solubility of hydrogen in iron at various temperatures. The results of Sieverts¹, Martin,² and Luckemeyer-Hasse and Schenck,³ given in Table I, are in fair agreement. These investigators all note the rapid increase in solubility of hydrogen in iron during the alpha-gamma transformation. Luckemeyer-Hasse and Schenck report an emission (that is, reduction in solubility) during the gamma-delta transformation which does not appear in the work of Sieverts. Luckemeyer-Hasse and Schenck believe the explanation for the greater solubility in gamma iron is found from Bragg's⁴ observation that in the face-centered cubic lattice there exists a "hole" in the center of the cube considerably larger than any free space in the body-

centered cubic lattice. In support of this it may be mentioned that Luckemeyer-Hasse and Schenck's curve for the solubility of hydrogen in delta iron is practically the prolongation of the curve for alpha iron.

Sieverts, whose tests were carried to temperatures beyond the melting point of iron, showed that molten iron has a much larger capacity for dissolving hydrogen than solid iron at the same temperature.

Using Sieverts' data for liquid iron, Luckemeyer-Hasse and Schenck have computed the absorption constant K for hydrogen in iron at atmospheric pressure and in weight per cent as follows:

$$\begin{aligned}\text{Alpha iron: } K &= 48 \times 10^{-6} \text{ } ^\circ\text{C.} - 17.2 \times 10^{-6} \\ \text{Gamma iron: } K &= 88 \times 10^{-6} \text{ } ^\circ\text{C.} - 37.2 \times 10^{-6} \\ \text{Delta iron: } K &= 60 \times 10^{-6} \text{ } ^\circ\text{C.} - 30.0 \times 10^{-6} \\ \text{Liquid iron: } K &= 275 \times 10^{-6} \text{ } ^\circ\text{C.} - 175.5 \times 10^{-6}\end{aligned}$$

The literature contains a number of references (5, 6, 7, 8, 9, 10) to iron hydrides. but experimental proof of their existence is not very convincing. Sieverts' considers

the reaction of hydrogen absorption by iron powder at high temperatures and at pressures over 100 mm. mercury to be a simple solubility process since the gas concentration in the metal is proportional to the square root of the pressure, while at lower temperatures and with finely divided iron, adsorption takes place.

Esser and Cornelius¹¹ have shown that hydrogen causes an additional cusp on the thermal differential curve of iron in the vicinity of the A₁ transformation. No satisfactory interpretation of this effect has been advanced.

Luckemeyer-Hasse and Schenck¹² and Naumann¹³ studied the effect of hydrogen on the physical properties of iron. It was conclusively shown that hydrogen greatly reduces the impact strength of iron; although the hardness was not materially changed. Bending tests performed by Heyn¹⁴ show the embrittling effect of hydrogen on iron.

For the removal of hydrogen from iron Esser¹⁴ believes that repeated heating through the critical range is more advantageous than heating at higher temperatures, since the evolution of gas is favored by the atomic rearrangements during transformation.

Wedding and Fisher¹⁵ and Luckemeyer-Hasse and Schenck¹² believe that the pressure in iron due to liberation of hydrogen can be great enough to cause rupture of the metal.

An equilibrium diagram for the iron-hydrogen system has not yet been proposed.

Lead-Iron—Isaac and Tammann¹ reported that liquid iron and liquid lead are practically mutually insoluble. The two metals are also mutually insoluble in the solid state. Tammann and Oelsen² gave the solubility of Fe in Pb as 2×10^{-4} to $3 \times 10^{-4}\%$.

Lithium-Iron—See barium-iron

Magnesium-Iron—See barium-iron

Mercury-Iron—Most of the data on Hg-Fe alloys pertain to solubilities and agreement on this point is lacking. Joule¹ reported 0.14-1.4% Fe soluble in Hg, Gouy² stated the solubility as less than 0.01% Fe at 15-18°C., Richards and Garrod-Thomas³ gave the value 0.00134% Fe, Tammann and Kollmann⁴ gave $1.15 \times 10^{-11}\%$ Fe at 170°C., and Palmaer⁵ reported 0.00007% Fe between 20° and 211°C. Brill and Haag⁶ found by X-ray examination that Fe-amalgams containing up to 25% Fe consist of a

suspension of alpha iron in Hg and this fact may account for the conflicting results of other investigators.

Osmium-Iron—Wever¹ lists this system (as well as the Ru-Fe system) as one wherein the gamma iron region is extended similar to the Fe-Ni system.

References

- ¹F. Wever, Ueber den Einfluss der Elemente auf den Polymorphismus des Eisens, Arch. Eisenhüttenw., 1928-29, v. 2, p. 739.

Palladium-Iron—The constitution of palladium-iron alloys was studied by Grigorjew.¹ The metals are completely soluble in each other in the liquid state and form a complete series of solid solutions, except there is perhaps a break at the composition corresponding to a compound of the formula FePd₃. Pd raises the temperature of the gamma-delta transformation and lowers the alpha-gamma transformation so that the diagram is quite like that for the Fe-Pt or Fe-Ni system.

Platinum-Iron—The characteristics of this system, which is similar to the Fe-Ni system, have been determined by Isaac and Tammann¹ as follows:

1. Iron and platinum are mutually soluble in all proportions in the liquid state.
2. A minimum in the liquidus curve occurs at about 1510°C. and between 10 and 20% Pt.
3. Pt lowers the temperature of the alpha-gamma transformation progressively such that at about 52% Pt the gamma phase is stable at room temperature.
4. A compound FePt, also identified by Nemilow² is believed to exist between 65% and 90% Pt.

Kussmann³ studied the coefficients of linear (thermal) expansion between 20 and 70°C. of certain Fe-Pt alloys annealed at 650°C. He found that the coefficient behaves anomalously with composition in a manner similar to the Fe-Ni alloys. The coefficient is negative between 50 and 60% Pt and passes through a minimum at 55% Pt.

Nemilow² measured the hardness and temperature coefficient of electrical resistance of Fe-Pt alloys. In the annealed alloys he found a maximum in the coefficient versus composition curve at 50 atomic per cent Pt.

Graf and Kussmann⁴ studied the magnetic properties of Fe-Pt alloys and reported the presence of ferromagnetism in the region of 30-70 atomic per cent Pt.

Potassium-Iron—See barium-iron.

Rhodium-Iron—Hansen¹ stated that it is probable that Rh and Fe form a complete series of solid solutions. Fallot² studied the alpha-gamma transformation in Rh-Fe alloys and found a minimum at 550°C. between 25 and 30% Rh.

Rubidium-Iron—See barium-iron.

Ruthenium-Iron—See osmium-iron.

Selenium-Iron—In this system Fonzes-Diacon¹ and Moser and Doctor² have studied the compound FeSe, which is the analogue of FeS. Alsen³ identified the structure of FeSe as being the same as NiAs. The X-ray investigations of Hagg and Kindstrom⁴ disclosed that at 50 atomic per cent Se the compound FeSe occurs and the alpha modification is stable below 300-600°C. Above this temperature range the beta form is stable. Alpha FeSe has a PbO (tetragonal) structure while the beta phase has the NiAs structure. The beta phase can dissolve Se up to 57.5% Se. On the basis of the above consideration, Hansen⁵ has constructed an equilibrium diagram.

Silver-Iron—Petrenko¹ stated that silver and iron are mutually insoluble. Tammann and Oelsen² determined that silver will dissolve $4 \times 10^{-4}\%$ Fe at 1000°C. and $6 \times 10^{-4}\%$ at 1600°C.

Sodium-Iron—See barium-iron.

Strontium-Iron—See barium-iron.

Tantalum-Iron—Jellinghaus¹ determined that Ta and Fe are mutually soluble in all proportions in the liquid state and a eutectic occurs at approximately 1400°C. between the iron-rich solid solution of 6-10% Ta and the compound FeTa. The solubility of Ta in alpha Fe decreases with decreasing temperature. According to Wever² the gamma field is closed at 4.25% Ta.

Recently the Ta-Fe system was studied by Genders and Harrison³. Their results appear to have been obtained with great care but are not concordant with the above. Genders and Harrison believe that errors in Jellinghaus' work are due to the presence of silicon (SiO₂ being reduced from the crucible by Ta). According to Genders and Harrison there are two eutectics, one at 20% Ta (approximately 1460°C.) between delta Fe solid solution and the compound Fe₂Ta, and the other at about 80% Ta between Fe₂Ta and the tantalum-rich solid solution. A lamellar eutectoid was found at 4.5% Ta and 1220°C. where delta breaks down to gamma (3% Ta) and Fe₂Ta. The solubility of Ta in gamma iron increases from about 0.6% at 974° to 4.5% at the eutectoid temperature. The solubility of Ta in alpha iron increases with temperature and amounts to about 1% at 974°C. Ta raises the temperature of the alpha-gamma transformation to 974°C. with 1% Ta but lowers the gamma-delta transformation to 1220°C at 3% Ta. The compound FeTa was not observed by Genders and Harrison, neither could they confirm the presence of the gamma loop.

Tellurium-Iron—According to Oftedal¹ there is a compound FeTe having the NiAs structure in this system.

References

- ¹I. Oftedal, Röntgenographische Untersuchungen von Manganarsenid, Eisentellurid, Nickelstannid und Platinstannid, Z. physik. Chem., 1928, v. 132, p. 208.

Thallium-Iron—Isaac and Tammann¹ concluded from their work on this system that thallium and iron are mutually insoluble in both the liquid and solid states and form no compounds.

References

¹E. Isaac und G. Tammann, Über das Verhalten von Eisen zu Blei, Wismut, Thallium, und Cadmium, *Z. anorg. allgem. Chem.*, 1907, v. 55, p. 61, Eisen-Thallium.

Tin-Iron—The essential points of the iron-tin diagram as now known may be summed up as follows: 1. There is a miscibility gap in the liquid state between 51% and 80% Sn according to Edwards and Preece¹. 2. In the tin-iron system there is a closed gamma loop. According to Wever and Reinecken² the alpha-gamma transformation is eliminated at 1.9% Sn. 3. The solubility³ of Sn in Fe is about 18% Sn at 1132°C. The solubility decreases with lowering temperatures. 4. Three compounds, FeSn, Fe₂Sn, FeSn₂, form by peritectic reaction.⁴ A diagram of the Fe-Sn system has been published by Hansen⁴.

⁴M. Hansen, Der Aufbau der Zweistofflegierungen, Julius Springer, Berlin, 1936, p. 740.

Titanium-Iron—The study of the iron-titanium equilibrium diagram is impeded by the difficulty of preparing pure Fe-Ti alloys. Lamort¹, whose alloys contained, in addition to TiN ("not more than 2%, as a rule less than 1%"), certain amounts of silicon (in three cases, 0.57, 0.90 and 1.12%) and aluminum (in three cases 1.15, 1.57 and 2.13%), determined that between about 5.4% to 22.2% Ti there occurs in this system a series of eutectiferous alloys consisting of the iron-rich solid solution and the compound Fe₂Ti (22.2% Ti). The eutectic was placed at 13.2% Ti and at 1298°C.

Seljesater and Rogers² studied the age hardening properties of iron-titanium alloys (0.5% to 7.1% Ti and containing "substantial amounts of Al and Si"), and concluded that the solubility of titanium in iron is approximately 6% at the eutectic temperature and 3% or less at room temperature.

Wever³ considers titanium in the group of metals that cause the formation of a gamma loop, and this is confirmed by Michel and Benazet⁴, who concluded that the alpha-gamma transformation disappears between 0.78% and 1.77% Ti.

By means of thermal analyses and X-ray examination Witte and Wallbaum⁵ investigated the iron-titanium system between 18% and 38% Ti. For the preparation of these alloys they used ferrotitanium of the composition 38.0% Ti, 0.7% P, less than 1.0% Si, less than 1.0% Al, 59.5% Fe; metallic titanium, melted (about 95% Ti); and Krupp WW iron. The amounts of impurities of the alloys are not stated. Witte and Wallbaum's results are not in agreement with Lamort, since they believe that the formula of the compound is Fe₂Ti (30.02% Ti). The melting point of Fe₂Ti was determined to be 1530°C., and its structure was reported to be isomorphous with MgZn.

Uranium-Iron—According to Hansen¹ the published work on the U-Fe alloys cannot be considered for determining their constitution since considerable amounts of carbon are present from the reduction of uranium ore by carbon. However, the work of Polushkin² may be mentioned, since it contains information as follows: 1. Uranium may form a compound Fe₂U. 2. Neither U nor the compound Fe₂U form solid solutions with iron. (Polushkin's alloys contained from 0.21 to 7.42% C and appreciable amounts of Si and V.)

Zirconium-Iron—From the work of Allibone and Sykes¹ and Vogel and Tonn² and others, Hansen¹ has published an equilibrium diagram which may be briefly described as follows: 1. The two metals are mutually soluble in all proportions in the liquid. 2. Two eutectics are formed one at 16% Zr and 1330°C. between gamma iron (0.7% Zr) solid solution and the compound Fe₃Zr₂, and the other at 88% Zr and 1350°C. with Fe₃Zr₂ and the beta Zr solid solution. 3. 0.3% Zr lowers the alpha-gamma transformation temperature to 835°C. The diagram published by Jänecke³ is in substantial agreement with the above.

Equilibrium Relations in Binary Iron Alloys—The very considerable fund of information existing for binary alloys of iron has brought forth some quite worth while attempts to correlate the ninety-one possible systems. As early as 1890 Osmond¹ noted a relation between the atomic volume of an element and its effect in iron alloys on the alpha-gamma transformation.

An especially interesting discussion of the application of concepts of alloy-ability to binary iron systems was written by Wever.² He recognized four types of binary diagrams whose differences were based on the character of the face-centered cubic gamma region.

In Type 1 the gamma-delta transformation line rises to meet the liquidus line while the alpha-gamma transformation line is gradually lowered to the concentration axis. The Fe-Ni diagram (see page 386) is an example of the first type. Besides Ni, Co, Ru, Rh, Pd, Os, Ir, Pt and Mn belong in this group.

The equilibrium diagrams of Type 2 have the familiar gamma loop and the body-centered cubic alpha phase occupies the major portion of the solid region. The Fe-Cr system (see page 374) is an example of Type 2, to which Wever also assigns Be, Al, Si, P, Ti, V, Ge, As, Cb, Mo, Sn, Sb, Ta and W.

The diagrams of Type 3 have divergent transformation lines which end in heterogeneous regions as represented by Fe-C (see page 366). N, Cu, Zn, and Au are also placed in this group.

Type 4 has a constricted gamma field, illustrated by Fe-S. In addition to S, B, Zr and Ce are found in this classification.

Wever also developed a relation between the atomic radii of the elements and their effect on the polymorphism of iron as differentiated above. The values for the atomic radii were not those computed from the lattice constants of the pure elements. They were modified according to the ideas of Goldschmidt,³ first to take into account the degree of ionization of the atoms of the element in its crystal lattice and second to correct for variation in co-ordination number.⁴ When these values were plotted against the corresponding atomic number a wave-like curve resulted at or near the peaks of which were found most of the elements insoluble in iron, while all the elements that widen the gamma field were situated in the troughs. Those elements that restrict the gamma phase were located principally at intermediate positions.

In this relationship Wever noted that "not so much the absolute size of the atom itself as the position in the atomic radii curve, or better the position in the periodic system, decides to which of the four groups of equilibrium systems of iron an element belongs". This, of course, is the effect of valence which Hume-Rothery⁵ showed so conclusively in his study of binary alloys of silver. The point is illustrated in Fig. 1.

⁴Number of nearest neighboring atoms, that is, in a body-centered cubic arrangement each atom has 8 equidistant neighbors.

A somewhat different classification based on rather ingenious diffusion experiments was made by W. D. Jones.⁴ Using the principle that a diffusion boundary is an indication of a phase change, Jones' classification is as follows:

1. Al, Sb, As, Be, Cr, Mo, P, Si, Sn, Ti, W, U,^b V, Zn,^c when allowed to diffuse into iron between 1000 and 1300°C, produced a diffusion boundary with columnar ferrite grains and presumably, therefore, the binary system of each element with iron includes a gamma loop.

Fig. 1—The types of binary iron alloys arranged in the periodic system of the elements. After Wever

Triangles: Elements insoluble in iron
 Square dots: Type 1 equilibrium diagrams
 Circular dots: Type 2 equilibrium diagrams
 Open squares: Type 3 equilibrium diagrams
 Open circles: Type 4 equilibrium diagrams

2. B, C, Co, Cu, Au, Ir, Ni, Mn and Ag, when allowed to diffuse into iron between 1000 and 1300°C., do not produce a diffusion boundary and presumably they tend to stabilize the gamma modification of iron.

3. Ba, Bi, Cd, Ca, Ce, Pb, Mg, Hg, K, Se, S, Ta and Te gave no evidence of diffusion in Jones' experiments, but he did not infer that no diffusion occurred.

Jones further noted that the heat of oxidation of each of the elements which inhibits the gamma phase is higher than that of iron and that, with the exception of manganese and boron, the converse is true.

The above correlations and others^{4, 7, 8} all contribute toward an understanding of the fundamental laws governing alloy systems. It is to be hoped more will be developed so that eventually our vast store of empirical knowledge of this subject may be completely systematized.

^cNote difference from Wever's classification.

a continuous curve formed by the lowering of A_1 and the raising of A_2 . The gamma field extends to 98.8 or 99% iron. The aluminum content required to close the gamma loop probably depends somewhat on the purity of the iron, particularly with respect to oxygen and carbon, as in the case of iron and silicon.²⁸

The dotted line of magnetic transformation is taken from Iwase and Murakami's results,²⁹ except that the A_2 point for iron has been definitely established at 769°C.²⁷ and the magnetic transformation curve consequently starts from this point. The A_2 transformation decreases slowly by the addition of aluminum up to 10%, and then rapidly until 16.5% content is reached, at room temperature.

More recently Sykes and Evans³¹ have shown that alloys in the region corresponding to the composition Fe_2Al (13.9% Al) "possess many interesting and hitherto unsuspected properties" depending upon whether the lattice structure occurs in a disordered or an ordered state. The change from the disordered to the ordered state can be prevented for compositions of less than 13.9% by quenching from 600°C. but not for higher aluminum contents.

The physical properties of iron-aluminum alloys up to 17% aluminum were investigated by Sykes and Bampfylde.³² They found that alloys from 0-5% aluminum are ductile and can be cold worked similar to pure iron. Alloys of 5-16% aluminum are brittle in ingot form and when cold. These alloys must be hot worked. Alloys above 17% cannot be worked.

Electrical resistivity curves show that alloys containing 12-16% of aluminum are affected by heat treatment whereas no effect occurs in those with from 2-12% aluminum. The general shape of the curves of the mean coefficient of expansion suggests that some form of transformation occurs in alloys having an aluminum content greater than 12% in the range of 500-600°C.

The lattice spacings of iron-aluminum alloys were studied by Bradley and Jay.³³ They found that both annealed and quenched alloys with from 0-10% aluminum have a random atomic distribution and show a linear increase in lattice spacing. The lattice spacings of alloys of 10-20% aluminum are anomalous and affected by heat treatment. Above 20% aluminum both the annealed and quenched alloys have the FeAl type of structure.

Alloys from 37-49.5% Aluminum—During solidification the solid solution ϵ is formed peritectically at 1210°C. (α solid solution + melt $\rightleftharpoons (\text{FeAl})_n \dots \epsilon$) which exists in the range from 49.5-40.5% Al and resolves into the θ and α solid solutions by the eutectoid reaction at about 1080°C. This eutectoid is of the lamellar type and is visible under the microscope in the unetched condition.

The line of eutectoid decomposition is shown by most of the earlier diagrams although within different concentration limits.

Alloys from 49.5-55% Aluminum—The solid solution θ , mainly consisting of the compound FeAl_3 , is formed peritectically at 1150°C. by the reaction between the melt and the ϵ phase (ϵ solid solution + melt $\rightleftharpoons \text{FeAl}_3 \dots \theta$). A noticeably large uniform range of the θ phase exists at the temperature just below the solidus though it becomes a smaller one at lower temperatures. The solid solution η , mainly composed of the compound Fe_2Al_3 , is formed also by a peritectic reaction (θ solid solution + melt $\rightleftharpoons \text{Fe}_2\text{Al}_3 \dots \eta$), at a temperature slightly lower than 1150°C.; this phase lies between 53 and 56% aluminum.

Kurnakow's³⁴ electrical conductivity measurements between 42.5-60.3% aluminum showed that these alloys have minimum conductivity and temperature coefficient and that there is but a slight difference in the conductivity values within this composition range. The possibility of single points corresponding to intermetallic compounds is therefore remote. Iwase and Murakami's diagram²⁹ showed a homogeneous phase between 43-59% aluminum which was considered a solid solution of iron in the compound FeAl_3 . This was, however, not in agreement with the thermal curves of alloys of this type shown by Gwyer.

Gwyer found in this range a decomposition in the solid state at 1158°C., which was, however, difficult to distinguish. Alloys containing 50-60% aluminum disintegrate to a powder within a few days when exposed to air.

Alloys from 55-59% Aluminum—The solid solution δ composed of FeAl_3 and existing at about 59% aluminum has a maximum melting point on the liquidus. The range of this solid solution at a high temperature is about 2-3% aluminum. A eutectic reaction is found to occur between the δ and η solid solutions, the eutectic temperature being slightly lower than that of the peritectic reaction: (Melt + $\theta \rightleftharpoons \eta$). The heterogeneous range between η and δ is confined to 56-59% aluminum.

Alloys containing 50-60% aluminum are viscous in the liquid and brittle in the solid state.

Alloy of 59.28% Aluminum—A slight maximum occurs in the liquidus curve. This alloy is homogeneous. Most investigators agree that this maximum corresponds to the intermetallic compound FeAl , although from electrical conductivity measurements by Broniewski there is no evidence of the existence of the compound FeAl . It is assumed that FeAl is a compound of the Berthollet type, whose chemical composition is not definite. This compound is extremely hard and brittle.

Alloys from 60-100% Aluminum—These alloys form a eutectiferous series. The eutectic alloy contains 98.11% aluminum with a freezing point of 653°C . This eutectic point was placed at 98-98.3% aluminum by different investigators at temperatures in the range between 648 and 655°C .

Constitution of Iron-Carbon Alloys

By R. S. Archer*

Cementite—Iron and carbon form a hard, brittle, crystalline compound, the composition of which is represented by the formula Fe_3C . This compound is referred to as iron carbide, or cementite. It contains 6.68% carbon by weight. Cementite crystallizes in the orthorhombic system, the unit cell containing 4 Fe_3C groups. The lattice parameter has been determined by Westgren and Phragmen,¹ by Wever,² and by Shimura³ on cementite crystals obtained from spiegeleisen. (The crystals probably contained some manganese and were, therefore, not pure iron carbide). The average values reported by these investigators are: $a_0 = 4.51 \text{ \AA}$; $b_0 = 5.06 \text{ \AA}$; $c_0 = 6.74 \text{ \AA}$. The average value for density corresponding to these determinations is 7.73, which is in good agreement with the value 7.74 obtained by Benedicks and 7.66 by Honeyman. The positions of the iron and carbon atoms in the cementite crystal as determined by Hendricks from the data of Westgren and Phragmen have been accepted by Westgren⁴ as probably correct. On heating above 1100°C ., iron carbide decomposes rapidly to iron and graphite. Its melting point has therefore not been observed but has been estimated at about 2000°C . Cementite undergoes a magnetic transformation at about 200°C .,⁵ designated A_6 .

Graphite—Under certain conditions, some of the carbon of iron-carbon alloys is present in the form of graphite, which is a distinct crystalline modification of the element carbon. Graphite is soft and friable. Graphite formed by annealing, as in malleable castings, is commonly referred to as temper carbon.

Allotropy of Iron—(See "Physical and Mechanical Properties of Iron," p. 424, this Handbook, for more detail). Solid iron is crystalline in structure, belonging to the cubic system. There are two distinct crystalline modifications of iron which are distinguished from each other by the arrangement of the atoms within the crystals. Each modification is stable only within certain ranges of temperature.

Modification	Crystal Structure		Range of Stability, °C.
Delta	Body-Centered	Cubic	1535-1400
Gamma	Face-Centered	Cubic	1400- 910
Alpha	Body-Centered	Cubic	910 and below

The appearance of the new crystalline form on heating or cooling through one of the critical temperatures is accompanied by complete recrystallization.

Iron undergoes certain discontinuous changes in physical properties in the neighborhood of 770°C . In particular, there is a marked decrease in magnetic properties on heating, this change being completed at 775°C .⁶ A slight evolution of heat on cooling, and a corresponding absorption on heating reach maximum intensity at 768°C . These changes are not accompanied by a change in crystal structure or by any corresponding phase change in the iron-carbon alloys.

Metallic Solid Solutions—Many metals possess the ability to dissolve certain other elements in the solid state, forming solid solutions which in many ways are analogous to ordinary liquid solutions. Ordinary brass, for example, is a solid solution of zinc in copper. Among the distinguishing characteristics of metallic solid solutions are: (1) Absence of definite atomic proportions; (2) capacity for change in chemical composition without abrupt change in physical properties; (3) ability of the dissolved elements to diffuse under suitable temperature conditions; (4) attainment of physical and chemical homogeneity when sufficient opportunity for diffusion is allowed.

It is probable that all metallic solid solutions are characterized by the atomic dispersion of the dissolved elements. When the atomic volumes of the solvent and solute elements are similar, as in the case of iron and nickel, it seems that the solute atoms replace atoms of the solvent, the space-lattice of which is retained. When the solute atom is markedly smaller than the solvent atom, as in the case of carbon and iron, it is quite probable that the solute atoms are in between atoms of the solvent.

Ferrite—Alpha iron is capable of holding in solid solution considerable amounts of various elements, such as nickel, silicon, and phosphorus. The maximum solu-

*Chief Metallurgist, Chicago District, Republic Steel Corp.

bility of carbon in alpha iron occurring at 723°C. (1333°F.) is approximately 0.035%.^{1, 4, 6} This decreases as the temperature falls to less than 0.01%^{10, 11} at room temperature. The varying solubility of carbon in alpha iron although slight, as shown by these figures, has appreciable effects on the properties of the iron-carbon alloys.

The term "*ferrite*" is applied to solid solutions in which alpha iron (or delta iron) is the solvent.

Austenite—Solid solutions in which gamma iron is the solvent are called *austenite*. Gamma iron dissolves carbon to a great extent. The maximum solubility at 2066°F. is 1.7%. This decreases with temperature to 0.80% at 1333°F.

Constituents and Phases—Those portions of an alloy which under the microscope appear to be definite units in the structure are called constituents. Thus the constituents of an annealed low carbon steel are ferrite and pearlite. Usually the term constituent is only applied to a portion of the alloy which appears homogeneous. Pearlite appears homogeneous at low magnifications, but at higher magnifications it is seen to be a mixture of alternate plates of ferrite and cementite. Another constituent, troostite, appears homogeneous at all except very high magnifications, at which it is seen to be similar in structure to pearlite but much finer. Sometimes the term constituent is applied to structural bodies which are easily seen to be mixtures, even at low magnifications. This is true of the austenite-cementite eutectic, called *Ledeburite*.

A phase is a portion of an alloy, physically and chemically homogeneous throughout, which is separated from the rest of the alloy by distinct bounding surfaces. The following phases occur in the iron-carbon alloys: Molten alloy, austenite, ferrite, cementite, and graphite. It will be noted that any of these phases may likewise be called a constituent. Not all constituents are phases, however, since some are mixtures and are not "physically and chemically homogeneous throughout."

Constitution—The constitution of an alloy is completely described when we state what phases are present and how much of each. The question of the arrangement of these phases is not involved. It is a sufficient description of the constitution of an annealed low carbon steel at room temperature, for example, to say that it contains 3% cementite and 97% ferrite, although a description of the structure of this steel might give the added information that it contains about 22% of pearlite and 78% of free ferrite.

The iron-carbon diagram deals only with the constitution of the iron-carbon alloys and not with their structure.

Equilibrium—The iron-carbon diagram represents alloys in a condition of equilibrium. It may be considered that a state of equilibrium exists in an alloy at any given temperature where exposure to that temperature for any further period of time does not produce any change in constitution, provided the temperature in question is sufficiently high to allow constitutional changes to go to completion. The test of equilibrium is that the same condition is reached, no matter from which side it is approached, whether heating or cooling.

How Diagram Is Plotted—In Fig. 1 the temperature is plotted vertically and composition horizontally. Any point in the diagram represents a definite alloy at a definite temperature. The carbon content of the alloy is shown on the horizontal axis directly below the point in question, while the temperature is shown on the vertical axis directly opposite the point.

The various lines of the iron-carbon diagram represent phase changes, as will now be described.

The Liquidus—The line "ABCD," called the liquidus, represents the beginning of solidification on cooling and the end of melting on heating. All points above this line represent alloys in a completely molten condition. All points below ABCD represent alloys partially or completely solid.

Solidification—Alloys containing from 0-0.55% carbon begin to solidify on cooling to the line AB by the separation from the liquid of crystals of delta iron containing in solid solution an amount of carbon indicated by the line AH. By this separation of delta iron, the melt is enriched in carbon until the peritectic line HJB is reached. If the composition is to the left of J, delta of composition H will undergo a peritectic reaction with the melt of composition B resulting in the solidification of austenite of composition J, and the amount of delta of composition H will be thus reduced. On further cooling to the line NJ, the delta ferrite will transform to austenite. If the composition is to the right of J, the delta of composition

H will transform to austenite of composition J and reduce slightly the amount of the melt of composition B. On cooling to JE, the molten phase will solidify to austenite. Alloys containing from 0.55-4.3% carbon begin to solidify on cooling to the line BC by the separation of austenite crystals from the liquid.

Alloys containing more than 4.3% carbon begin to solidify with the separation of cementite from the liquid, on cooling to the line CD.

The alloy containing 4.3% carbon is the eutectic alloy and solidifies entirely at the point C, with the simultaneous formation of austenite and cementite.

In the case of alloys containing 0.55-1.7% carbon, austenite continues to freeze out on cooling from JBC to JE. At JE the alloy is completely solid and consists of one phase, austenite.

In alloys containing from 1.7-4.3% carbon, austenite freezes out of the liquid from BC to EC. At EC there is some residual liquid, which is of eutectic composition. This liquid then solidifies at constant temperature, forming the eutectic mixture of austenite and cementite.

In alloys containing more than 4.3% carbon, cementite freezes out on cooling from CD to CF. At CF the residual liquid is of eutectic composition and solidifies at constant temperature.

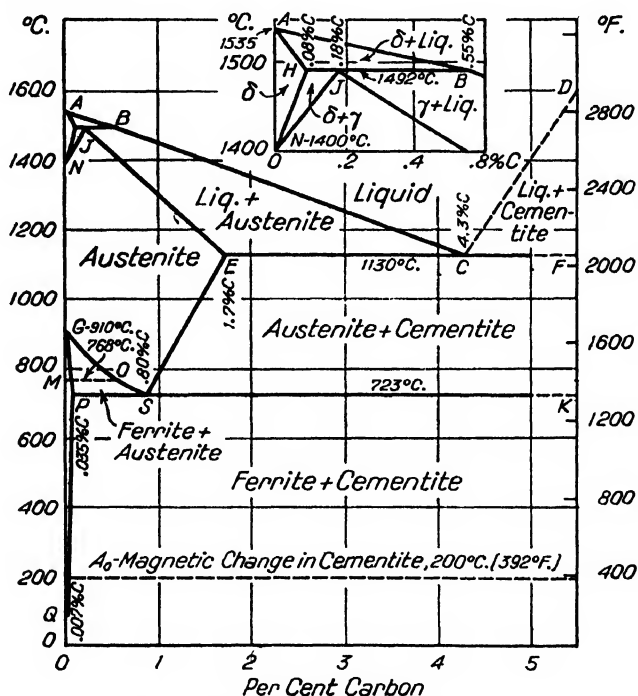

Fig. 1—Iron-Carbon Constitution Diagram.

The Solidus—The line AHJEF is called the solidus. Below this line all alloys are completely solid.

Ferrite Solubility Curve—The temperature at which alpha iron forms from gamma iron on cooling is lowered by the presence of carbon in solid solution in the gamma iron, that is, in austenite. This is represented in the diagram by the line GS, which shows that the temperature of formation of ferrite decreases from 1670°F. for pure iron to 1333°F. for an alloy containing 0.80% carbon. The formation of ferrite from the solid solution austenite is analogous to the precipitation of a salt from its solution in water. The line GS thus expresses the solubility of ferrite in austenite, and may be referred to as the ferrite solubility curve.

The dotted line MO represents the discontinuous change in the physical properties of alpha iron at about 768°C. It does not represent a phase change in the

iron-carbon alloys. The thermal arrest occurs at MO, and in alloys of higher carbon content is merged with the other arrests corresponding to the line OSK. Some diagrams show a sharp break in the ferrite solubility curve GOS at the point O. There seems to be sufficient evidence that GOS should be slightly curved, as shown in Fig. 1, but a sharp break at the point O is questionable. When austenite containing less than 0.80% carbon is cooled to temperatures represented by the line GOS, ferrite separates from solution. Since the ferrite is almost carbon-free iron, its separation results in an enrichment of the remaining austenite in carbon. This causes a progressive lowering of the temperature at which ferrite separates out, and the austenite constantly diminishes in amount and becomes richer in carbon. Consider a steel containing 0.40% carbon. At 1650°F. this steel consists entirely of austenite. On cooling to about 1435°F. ferrite begins to form, and continues to separate from the austenite as the steel cools further. When a temperature of 1333°F. is reached, the steel consists of one-half ferrite containing practically no carbon and one-half austenite containing 0.80% carbon.

Cementite Solubility Curve—At the eutectic temperature, 2066°F., austenite will hold 1.7% of carbon in solid solution. When austenite of this composition is cooled, cementite precipitates from solution. The solubility of carbon in austenite at various temperatures is shown by the line SE, which may be called the **cementite solubility curve**, as cementite is the phase which is precipitated.

When a steel containing more than 0.80% carbon is cooled from a temperature at which it is austenitic, cementite begins to deposit at the line SE. Since cementite contains 6.68% carbon, its precipitation causes a lowering of the carbon content of the austenite. This lowers the temperature at which cementite precipitates, and the cooling of the steel results in a progressive precipitation of cementite and a progressive decrease in the carbon content of the austenite. This continues until a temperature of 1333°F. is reached, and the residual austenite then contains 0.80% carbon.

The Eutectoid—No matter what carbon content is started with, austenite reaches a temperature of 1333°F. on slow cooling with a carbon content of 0.80%.

On cooling through this temperature austenite containing 0.80% carbon deposits simultaneously a mixture of ferrite and cementite. This mixture is called the **eutectoid**, from analogy to the eutectic.

The eutectoid temperature 1333°F. is the temperature at which austenite is simultaneously saturated with both ferrite and cementite. This is represented in the diagram by the intersection of the ferrite solubility curve GS with the cementite solubility curve SE, at the eutectoid point S.

Pearlite—With moderately slow cooling, the decomposition of austenite containing 0.80% carbon results in the formation of a constituent in which the ferrite and cementite occur as alternate thin lamellae. These lamellae refract light in a similar manner to the lines of a diffraction grating, giving the constituent a pearly appearance, from which it has received the name **pearlite**.

Reversibility of Phase Changes—The phase changes which occur on cooling, as described above, are reversed on heating. For example, on heating pearlite through 1333°F. the ferrite and cementite redissolve to form austenite. Considering the 0.40% carbon steel again, we have at room temperature a mixture of approximately equal parts of ferrite and pearlite. On heating to the line PSK (Fig. 1) this pearlite changes at constant temperature to austenite of eutectoid composition; the ferrite is unaffected.* On heating above PSK the ferrite gradually dissolves in the austenite until all of the ferrite is dissolved on crossing the line GS, and the austenite contains 0.40% carbon.

The Critical Points—The phase changes described liberate heat when they take place on cooling, and absorb heat on heating. These evolutions and absorptions of heat are shown by halts or arrests in cooling curves and heating curves, which indicate the temperatures at which the changes take place, and are usually called the **critical points**.

The method of designating the various points, which is borrowed from the French, needs a word of explanation. The halt or "arrest" in cooling or heating is designated by the letter A, standing for the French word *arrêt*. An arrest on cooling is referred to by the letters Ar, r standing for *refroidissement* = cooling. An arrest on heating is designated by the letters Ac, the c standing for *chauffage* = heating. The

*Except for dissolving the traces of carbon soluble below A1.

various arrests are distinguished from each other by numbers after the letters, being numbered in the order in which they occur as the temperature increases, as follows:

Arrest	Temp. °F.	Significance
A0	390	A magnetic change in cementite. Probably not a phase change. Hence shown in diagram by dotted line.
A1	1333	The eutectoid transformation.
A2	1414	A change in the magnetic and certain other properties of alpha iron. Not a phase change.
A3	1333-1670	The beginning of the precipitation of ferrite from austenite on cooling, or the end of its solution on heating.
A4	2552 (in pure iron)	The change from gamma to delta iron on heating, and vice versa on cooling.

When the critical point or the recalescent point is mentioned, it is usually the temperature of the eutectoid transformation, A1, that is meant.

Lag—The temperatures given above and in the diagram refer to conditions of equilibrium. Under practical conditions there is a delay or lag in the attainment of equilibrium, and the critical points are found at lower temperatures on cooling, and at higher temperatures on heating, than those given. That is, there is a difference between the Ar points and the Ac points. This difference increases with the rate of cooling or heating. The equilibrium temperatures correspond to very slow cooling or heating.

Classification of Alloys—Steels containing less than 0.80% carbon are called **hypoeutectoid steels**. Steel containing approximately 0.80% carbon is called **eutectoid steel**, or steel of eutectoid composition. Steels containing more than this amount of carbon are called **hypereutectoid**. Alloys containing less than 4.3% carbon are **hypo-eutectic alloys**; alloys containing more than 4.3% carbon are **hypereutectic alloys**. The alloy containing 4.3% carbon is the eutectic alloy.

Phase Fields—While the various lines of the constitution diagram represent phase changes, the areas bounded by these lines represent conditions of temperature and composition under which certain phases are stable. The phases stable within the various fields of the diagram are as follows:

Above ABCD	Liquid Solution	DCF	Cementite + Liquid
AHB	Delta + Liquid	NJESG	Austenite
AHN	Delta Iron Solid Solution	GSP	Ferrite + Austenite
HJN	Delta + Gamma	ESKF	Cementite + Austenite
JBCE	Gamma + Liquid	Under PSK	Ferrite + Cementite
		GPQ	Alpha Ferrite

Proportions of Phases—The amount of a certain phase present in a given alloy at a given temperature can be calculated in accordance with the following principle and examples: Determine the number of units on the composition axis between the points at which the alloy consists entirely of the phase in question, that is, the point at which the quantity of this phase is 100%, and the point at which the quantity of this phase has just decreased to 0.00%. Represent this number of units by the letter M. Determine the number of units on the composition axis between the composition of the alloy in question, and the point at which there is 0.00% of the desired phase. Represent this number by the letter N. Then the amount x of the desired phase, expressed in per cent, is

$$x = \frac{N}{M} \times 100$$

If the compositions expressed by the letters "M" and "N" are in weight percent, then the amount "X" of the desired phase will also be in weight percent. In the case of the iron-carbon alloys, however, the density of cementite is so close to that of iron, that "X" will also closely represent the volume percentage of the desired phase. In alloys whose constituents differ markedly from each other in density, a more general method of calculation must be employed which takes into account the densities of the various constituents.

For example, it is desired to calculate the amount of cementite in the austenite-cementite eutectic immediately after solidification; that is, at the eutectic temperature. With 6.68% carbon the alloy is 100% cementite. As the carbon is decreased the

amount of cementite decreases, becoming zero at 1.70% carbon, which is the amount soluble in iron at this temperature. The quantity M referred to above is then $6.68 - 1.70 = 4.98$. The eutectic alloy is $4.30 - 1.70 = 2.60$ units from the point of zero cementite. Then

$$\frac{2.6}{4.98} \times 100 = 52\% \text{ cementite in the eutectic alloy,}$$

$$100 - 52 = 48\% \text{ austenite in the eutectic alloy}$$

Description of Phases According to Origin—The austenite that freezes out of hypoeutectic alloys above the eutectic temperature is usually distinguished as **primary austenite**. The austenite of the austenite-cementite eutectic is referred to as **eutectic austenite**. Likewise, the cementite which freezes out of alloys containing more than 4.3% carbon is called **primary cementite**, and the cementite of the eutectic is called **eutectic cementite**. The ferrite which forms from hypoeutectoid austenite at GS is called **proeutectoid ferrite**, and the cementite which precipitates along SE is **proeutectoid cementite**. The ferrite and cementite of the eutectoid itself are described as **eutectoid** or **pearlitic**. Thus there are two kinds of ferrite from the structural standpoint, and four kinds of cementite distinguished by their origin.

Structural Constitution—The quantities of the structural constituents present in an alloy can also be calculated with the help of the equilibrium diagram, using the principle illustrated above.

Suppose it is desired to calculate the amount of pearlite in a 0.35% carbon steel at room temperature. The carbon content corresponding to 100% pearlite is 0.80%. Assuming that the solubility of carbon in iron at room temperature is zero, which is practically the case, the point at which the amount of pearlite decreases to zero is 0.00% carbon. Then $M = 0.80 - 0.00 = 0.80$.

$$N = 0.35 - 0.00 = 0.35$$

The amount of pearlite in the steel

$$= \frac{N}{M} \times 100 = \frac{0.35}{0.80} \times 100 = 44\%$$

The amount of ferrite in the steel = $100 - 44 = 56\%$.

A steel containing 1.7% carbon, after cooling at a normal rate to room temperature, is composed of pearlite and proeutectoid cementite. The amount of this cementite can be calculated as follows: The carbon content at which the structure would consist entirely of cementite is 6.68% (the composition of pure cementite). The carbon content at which the proeutectoid cementite decreases to zero is 0.80%. Then $M = 6.68 - 0.80 = 5.88$. $N = 1.70 - 0.80 = 0.90$. The quantity of proeutectoid cementite in the 1.70% carbon steel is then

$$\frac{N}{M} \times 100 = \frac{0.90}{5.88} \times 100 = 15\%$$

The amount of pearlite in the steel is $100 - 15 = 85\%$. Since 1.7% carbon is the maximum amount soluble in austenite, 15% is the maximum amount of proeutectoid cementite possible.

Effect of Other Elements—All commercial steels contain more or less manganese, phosphorus, sulphur and silicon. Most commercial steel also contains residual amounts of copper and nickel. The data on temperature and composition which are represented in the iron-carbon diagram refer to iron-carbon alloys containing extremely low amounts of other elements. The amounts of these other elements which are present in commercial steel may alter appreciably the location of the various lines in the diagram. When still larger amounts are present, even the form of the diagram may be substantially changed. The constitutions of various binary alloys of iron are discussed in the articles immediately following this one. It is hoped that it will later be possible to present complete data on the constitution of the ternary alloy systems comprising iron, carbon and one other element. The effect

of this other element on the constitution of the iron-carbon alloys will then be completely described.

Stable vs. Metastable Equilibrium—Under certain conditions the carbon of iron-carbon alloys occurs as graphite. This is favored by extremely slow cooling, a condition which in general favors the establishment of stable equilibrium. It is, therefore, generally considered that iron and graphite represent the ultimately stable phases of the iron-carbon system, and that the occurrence of iron and cementite represents metastable equilibrium. Accordingly, alloys which at various temperatures consist of austenite and graphite, or of ferrite and graphite, with no cementite, are said to constitute the **stable system**. Alloys containing cementite but no graphite, which have been described above, are said to constitute the **metastable system**.

Phases of Stable System—The phases of the stable system are: (1) Liquid alloy; (2) austenite; (3) ferrite; and (4) graphite. It will be noted that the first three of these also occur in the metastable iron-cementite system.

Effect of Composition on Graphitization—The formation of graphite is favored by the presence of silicon, nickel and aluminum. In practice it is difficult to produce graphite in strictly pure iron-carbon alloys. The occurrence of graphite in such products as gray cast iron, malleable iron, and tool steel is usually due to the presence of silicon.

Graphitization is opposed by the presence of carbide forming elements such as chromium and manganese. Sulphur as iron sulphide strongly opposes graphitization, but is inactive when present as manganese sulphide. The first additions of manganese, therefore, favor graphitization by neutralizing sulphur. For a given composition of alloy with respect to elements

other than iron and carbon, graphitization takes place more readily the higher the total carbon.

Diagram for Stable System—The constitution diagram of the iron-graphite system is shown in Fig. 2 in full lines, the dotted lines representing the equilibria of the iron-cementite system.

In the case of three lines, AC, AE, and GS, the dotted lines and full lines coincide. This is because these lines represent equilibria between those three phases which are common to the two systems.

The rest of the diagram, in which the dotted lines and full lines do not coincide, merely expresses the fact that at all temperatures the solubility of graphite in iron is less than that of cementite in iron. Accordingly the eutectic and eutectoid temperatures of the iron-graphite system are higher than for the iron-cementite system.

The diagram is qualitative in that it does not represent the exact differences in solubility and temperature. These differences are relatively slight. Wells¹² has made careful determinations in the region around the eutectoid, using alloys of high purity, and Mehl and Wells¹³ investigated metastable (iron-cementite) equilibria in the same alloys. They place the eutectoid at 0.80% carbon in the metastable system, and at 0.69% carbon in the iron-graphite system; the eutectoid temperature at 723°C. for iron-cementite, and at 738°C. for iron-graphite.

Graphite and Cementite Together—Both stable and metastable equilibria may be represented in the same alloy, as illustrated by the following example:

Well annealed malleable castings consist almost entirely of ferrite and graphite and, therefore, belong entirely to the stable system. Suppose a piece of malleable cast iron containing 2.40% graphite is heated to 1600°F. The graphite will begin to dissolve in the iron, forming austenite. This process will continue until the carbon content of the austenite reaches a value represented by a point where a 1600°F. horizontal intersects the graphite solubility curve S'E', that is, at about 1.00%. When this solution process comes to rest the alloy is in a state of equilibrium, the equilibrium belonging to the stable system. Now if the alloy is cooled slowly to room temperature, a rate of about 10-20°F. per hr. being required for

Fig. 2—Stable and Metastable Equilibrium Diagrams. The Dotted Lines Represent Metastable Equilibrium and the Solid Lines Represent Stable Equilibrium. For simplicity, some details which are not pertinent to the iron-graphite system are omitted from this diagram (see Fig. 1).

ordinary malleable, graphite will be reprecipitated. However, if the alloy is cooled moderately fast, as by air cooling, only a little graphite will be formed from the 1.00% of carbon dissolved in the austenite. Most of this carbon will precipitate as cementite, forming pearlite on passing through A_1 . This pearlite belongs to the metastable system.

Ordinary cast irons, which generally contain both graphitic and "combined" carbon, represent a combination of stable equilibrium, attained or approached at the higher temperatures, and metastable equilibrium, produced by the more sluggish phase changes at the lower temperatures.

Remarks—Attention is called to the fact that the diagram here given represents conditions of equilibrium in iron-carbon alloys of the highest purity available to the various investigators upon whose work the diagram is based. Small amounts of impurities have appreciable effects upon temperatures at which the phase changes occur, and it has not been easy to prepare and work with iron-carbon alloys of such purity that the impurities present could be said to have no appreciable effects. Oxygen, in particular, is difficult to eliminate. Temperatures are altered, and changes represented in the diagram as occurring at constant temperature may take place over an appreciable range of temperature. In commercial steels the pearlite change at A_1 , for example, takes place over a range of temperature instead of at a constant temperature, as represented in the diagram by the line PSK.

The carbon contents and temperatures which define the various points in the diagram have been selected after a review of the work of the various investigators in this field. The reader who has further interest in the subject is referred to a very thorough and critical review of the subject in the monograph on iron-carbon alloys.¹⁴

It will be noted that all of the lines in the diagram are drawn straight, with the exception of the line GOS. It is probable that most of these lines, with the exception of the horizontals, are curved, but it is considered that there is insufficient evidence at present on which to base the construction of lines having a definite degree of curvature. The line GOS, it seems, should be definitely curved in the direction shown and approximately to the extent shown.⁴

Constitution of Iron-Chromium Alloys

By Edgar C. Bain* and Robert H. Aborn**

Introduction—The fundamental concept of an iron alloy system wherein the alloying element is more soluble in alpha or delta iron than in gamma iron, and which, therefore, has a limited composition range for stable austenite, is so essential to the understanding of the iron-chromium system that reports of the early investigators who did not recognize this possibility need not be considered here. Probably anticipated by Tammann¹ and certainly predicted by Hanson² and Oberhoffer³, the existence of the gradually restricted (and finally suppressed) temperature range of stability for the gamma iron solid solution was first definitely determined by Wever⁴. With Gianl and Reineken he constructed the equilibrium diagrams for the iron-silicon and the iron-tin systems which, like the iron-chromium series, exhibit the "austenite loop"; a very important contribution to ferrous metallography. Shortly thereafter, the same characteristic in the iron-tungsten and iron-molybdenum systems was independently discovered and announced by Sykes⁵ who accurately constructed their equilibrium diagrams, and the austenite loop in iron-chromium alloys was found by Bain⁶.

Fig. 1—Iron-Chromium Constitution Diagram contributed to by various investigators.

Fig. 1 illustrates the growth of the diagram as contributed to by various investigators.⁷ The original view that chromium raises the A_3 temperature even when present in small amounts was based upon tests on impure alloys and was rejected with further evidence. Recent studies by the present authors under proven equilibrium conditions and dilatometric researches¹⁰ corroborate the Oberhoffer and Esser³ loop rather than Kinzel's⁸ horizontal A_3 line. Adcock's⁹ liquidus and solidus appear more probable than that of Oberhoffer and Esser, although the melting point¹⁰ of chromium seems somewhat uncertain. Wever and Jellinghaus¹¹ corroborate the existence of the brittle compound. The region of the compound is left uncertain (dotted) in the diagram because of certain ambiguities in the interpretation of the data. As in the iron-aluminum and iron-silicon alloys, very large physical effects seem to result from a pre-precipitation stage of the compound formation and the representation of this condition in a phase diagram is still an undecided question.

Characteristics of the Iron-Chromium Alloy Series—The authors have drawn the diagram in Fig. 2 as representing a probable best compromise. While certain refinements will doubtless entail future revision, the diagram is not believed to be seriously in error. The principal characteristics of the iron-chromium alloy series are as follows:

1. The melting range shows a single noneutectiferous minimum, at which solidus and liquidus are tangent, characteristic of homogeneous isomorphous series.
2. Delta iron and chromium are completely miscible in all proportions in the solid state, and form therefore, at elevated temperature, a complete series of homogeneous solid solutions.

*Asst. to Vice Pres. and **Research Laboratory, United States Steel Corp., Pittsburgh, Pa., and Kearny, N. J.

3. Gamma iron, even at the temperature of its greatest chromium dissolving capacity (925-950°C.) holds only about 12.8% chromium in saturated solid solution.

4. Increasing chromium content rapidly lowers the A_4 or delta \rightleftharpoons gamma transformation temperature, and likewise in proportions up to about 7 or 8% lowers the A_2 or alpha \rightleftharpoons gamma transformation; beyond this, higher concentration of chromium, while it continues to lower the A_4 temperature, rapidly raises the A_2 temperature until A_2 and A_4 coincide.

5. The A_2 transformation which, for pure iron, occurs at a single constant temperature requires a range of temperature in iron-chromium alloys, a circumstance necessitating a two phase (alpha + gamma) region in the equilibrium diagram. This temperature range, however, of the mixed structure is narrow and vanishes at the single composition (about 7 or 8% chromium) corresponding to the minimum A_2 temperature. All compositions, excepting pure iron, show a temperature range for the A_4 transformation, with the corresponding delta + gamma field in the diagram.

The very circumstance of the disappearance of transformation in alloys carrying more than about 12.8% chromium forces the conclusion that alpha iron and delta iron are in reality the same phase of crystalline entity. This point is of sufficient significance to warrant consideration. If chromium be added continuously to iron, at for example, 800°C. (hence to alpha iron or ferrite) then no phase change is encountered even when an alloy of 18 or 20% chromium is reached. If such an alloy is heated to a very high temperature (1425°C.) no change of phase occurs; and if gradually the chromium content is reduced to zero, the same phase is still preserved and the final pure iron is in the so-called delta condition. The lattice parameter of the crystal unit of pure iron at this temperature (2.93Å) is in accord with the observed thermal expansion of alpha iron from its room temperature crystal dimension (2.860Å). Alpha iron and delta iron are therefore in reality the same allotropy.

Fig. 2—Iron-Chromium Constitution Diagram representing best compromise from various investigators. (Bain and Aborn.)

6. The temperature of rapid magnetic change in iron (A_2) is, except for a possible slight elevation accompanying the first small additions, uniformly lowered by increasing chromium content.

7. In all probability a compound, FeCr, is formed in alloys carrying more than perhaps 30% and less than 55% chromium. The rate of the transformation of ferrite to this brittle phase (B constituent)¹² is extremely slow in pure alloys unless cold worked,¹³ but rapid in the presence of a few per cent of nickel and other elements. The rate of formation of FeCr is the more rapid the nearer the temperature is maintained to its upper limit of stability. The constituent when developed appears to be converted to ferrite at temperatures above about 900°C. even for the pure constituent, and at lower temperatures when it forms only part of the alloy. For example, a temperature of about 700°C. destroys the phase when developed in a 30% chromium alloy. The compound, as would be expected, is extremely hard and brittle, and is nonmagnetic. Although several investigators offer evidence for the existence of this compound (see references 13, 14, 15, 16, 17 and 19), Adcock has not been able to verify it in his purest alloys.

8. All iron-chromium alloys containing even up to about 40% chromium are

(in the absence of the brittle phase FeCr) definitely plastic even at ordinary temperature. The malleability and plasticity decreases with increasing chromium content and grain size. At high temperature the alloys are forgeable with chromium up to 60 or 70%; even pure chromium exhibits definite high temperature plasticity.

9. The alloys containing less than about 12.8% chromium, and therefore exhibiting allotropy, are definitely hardened by quenching from temperatures establishing the gamma iron solid solution. The higher chromium alloys in this range undergo greater hardening by quenching, which forms a carbonless martensite with definite acicular markings as observed microscopically. Alloys carrying more than about 5% chromium may be quenched from temperatures which establish the high temperature alpha iron solution (δ ferrite), without any transformation, to yield unchanged the high temperature structure. The allotropic change to austenite, and its reversion, is thereby obviated entirely.

10. Carbon, nickel, manganese, and cobalt when present in the iron-chromium alloys rapidly increase the maximum chromium solubility in the gamma iron solution (austenite); whereas silicon, tungsten, molybdenum, vanadium, aluminum, tantalum, and phosphorus, reduce the chromium solubility in austenite. The ternary iron-chromium-carbon system is relatively complex due to the formation of several different carbides and to the unusual circumstance of the existence at equilibrium of carbide and ferrite in contact at high temperature with no austenite.

11. When about 11.5% chromium is present in homogeneous solid solution in iron the resultant alloy is substantially unattacked in many oxidizing environments. The abruptness of the acquisition of this corrosion resistance from the standpoint of composition calls to mind the Tammann rule of eighths since the critical composition for this passivity is practically 1 atom of chromium to 7 of iron—1 in 8. The corrosion resistance is believed to be effected by a passive surface layer containing oxygen, and is a characteristic common to all members of the stainless steel family.

Constitution of Iron-Copper Alloys

By J. L. Gregg* and B. N. Daniloff†

General—The iron-copper diagram has assumed a new importance because of the recent discoveries that marked precipitation hardening can be produced in the iron-rich alloys and that the quenching preceding the aging treatment need not be at all drastic, thus making it possible to harden the alloys by merely reheating the air cooled specimens to a temperature at which precipitation occurs. The diagram is also interesting because its liquid immiscibility field appears to be unique among metallic systems.

As a part of the Alloys of Iron Research program the literature on the alloys of iron and copper was reviewed by the authors, while at the Battelle Memorial Institute, and the results were published in the book "Alloys of Iron and Copper" in 1934. A thorough search of the literature in connection with this work has proved that the available data are not sufficiently reliable and consistent to permit the construction of an accurate and certain iron-copper equilibrium diagram, but what is believed by the authors to be the most probable diagram has been drawn and is described at right.

Review of Early Work on Iron-Copper Diagram—Though earlier workers had studied iron-copper alloys, an attempt to actually determine the iron-copper diagram was first made by Sahmen¹ in 1908. In disagreement with some of the earlier observers, notably Pfeiffer², he found that the alloys were completely miscible in the liquid state. Work of Ruer and Fick³ and Ruer and Goerens⁴, reported in 1913 and 1917 respectively, definitely established the fact that 2 liquid layers could occur in the iron-copper system. Presumably accurate thermal analyses, however, failed to indicate a horizontal portion of the liquidus required by the phase rule when alloys melt to form 2 conjugate liquids. In commenting on iron-copper alloys in 1925, Ostermann⁵ pointed out that the discordant results of the various investigators and the inconsistency with the phase rule would be explained if the region of liquid immiscibility approached but did not intersect the liquidus. This hypothesis was in part supported by the observation of Ruer and coworkers that the region of immiscibility narrowed as the temperature decreased. Experimental data secured by Müller⁶ also supported Ostermann's hypothesis, although Ruer⁷ was not convinced that the field of liquid immiscibility was closed at the low temperature. A recent investigation by Maddocks and Claussen⁸ indicated that there is no liquid immiscibility at temperatures as high as 1570°C. in alloys containing almost no carbon.

Iron-Copper Constitution Diagram—In the constitution diagram given in Fig. 1 the region of immiscibility is shown as closed at about 20°C. above the liquidus. As far as the authors are aware, this is the only known binary metallic system in which alloys of all compositions melt to form a single liquid but in which alloys within a given range of composition separate into two conjugate liquids as the temperature is raised. This behavior has been observed in a number of nonmetallic systems.

No compounds are formed in the iron-copper system, and the solid phases pres-

Fig. 1—Iron-Copper Constitution Diagram.

*Bethlehem Steel Co., Bethlehem, Pa.

†United States Navy Yard, New York

ent are merely a solution of one component in the other. In the diagram they are described as follows:

- delta—iron-rich phase with body-centered lattice stable at high temperatures.
- gamma—iron-rich phase with face-centered lattice, the "austenite" of this system.
- alpha—iron-rich phase with body-centered lattice stable at low temperatures, the "ferrite" of this system.
- epsilon—the copper-rich phase, containing not more than 4% iron.

The iron-rich portion of the iron-copper system is strikingly similar to that of the iron-carbon system. Like iron-carbon alloys, in certain concentrations the melt reacts peritectically with the delta phase to form the gamma phase. The temperature of this reaction as determined by Ruer and Klesper⁸ is 1477°C. In the diagram, delta solid solution of composition h reacts with melt of composition b at this temperature to form gamma solid solution of composition i.

The Eutectoid—A eutectoid occurs in the iron-copper system in which the gamma solid solution is converted into alpha and epsilon solid solutions. The eutectoid point is shown as p in the diagram and the alpha and epsilon phases in equilibrium with the gamma phase at the eutectoid temperature are represented as o and q respectively. Ruer and coworkers found the eutectoid temperature to be 833°C. and located point p at 2.3% copper, but Buchholtz and Köster⁹ gave the temperature as 810°C.

Fig. 2—Solubility of copper in alpha iron. (Buchholtz and Köster.)

phenomenon does occur. However, Vogel and Dannöhl¹⁶ in a recent publication reported that the solubility of copper in gamma iron is 8% at 1470°C. and increases to 8.5% at 1094°C.

A second peritectic reaction occurs at 1094°C. in which melt of composition e reacts with gamma of composition l to form epsilon of composition m, as was established by Ruer and coworkers.

The temperature of magnetic transformation, as determined by Ruer and coworkers, is shown by the line rtu.

The solubility of copper in alpha iron below the eutectoid temperature and the solubility of iron in copper decrease with decreasing temperature, thereby suggesting the possibility of dispersion hardening in both iron-rich and copper-rich alloys. As was shown by Hanson and Ford,¹⁰ the degree of dispersion hardening that can be produced in copper-rich alloys is not great, but recent workers, including Kinneer,^{11, 12} Nehl,¹³ and Buchholtz and Köster,⁹ have shown that marked precipitation hardening can be produced in the iron-rich alloys. It has also been found that the iron-rich alloys need not be drastically quenched in order to bring about supersaturation at room temperatures, and remarkable hardening can be produced by air cooling, followed by reheating in the neighborhood of 600°C.

and the concentration as 5.5% copper. The latter values were used in drawing the diagram, but it is not known whether or not they are more reliable than the others. A recent investigation by Norton¹⁵ indicated that the eutectoid was in the neighborhood of 850°C., but this transformation temperature was not determined with certainty.

Phases of Iron-Copper System—Line np corresponds to the A_1 line of the iron-carbon system. Along this line the alpha phase whose composition is represented by line no is formed on cooling. Line lp corresponds to the A_{cm} line of the iron-carbon system. Along this line, epsilon phase of composition mq is formed on cooling.

Line il, separating the gamma from the gamma plus liquid phase, has not been accurately determined. If its direction is as shown, certain alloys partially melt on cooling, and according to Ostermann⁶ this surprising

The solid solubility of copper in alpha iron as shown by xto in Figs. 1 and 2 is as given by Buchholtz and Köster. In a recent determination of this line by X-ray diffraction methods Norton found that the solubility of copper in iron at the eutectoid temperature and temperatures down to 650°C. was appreciably less than that indicated in the diagram. According to Norton the limit of solubility of copper in alpha iron at the eutectoid temperature (point O) is only 1.4%, and the solubility at 650°C. and lower is 0.35%.

Constitution of Iron-Manganese Alloys

By Dr. V. N. Krivobok* and Dr. Cyril Wells†

General—Since the publication of the comprehensive studies of iron-manganese alloys, the last of which appeared in June, 1936, no further work appears to have been done and, consequently we are still lacking complete understanding of the iron-manganese system. For example, the relationship, under equilibrium conditions, between the epsilon phase (presently to be described) and other phases is not yet known.

In common with many metallic systems, alloys of iron and manganese exhibit a marked tendency for hysteresis between the phase transformations on heating and cooling. Thus, the study of equilibrium conditions at various temperatures is complicated and much care in interpreting experimental observations is required if erroneous conclusions are to be avoided.

The iron-manganese phase diagram is reproduced in Fig. 1. It is believed that this diagram represents most accurately the constitutional changes which take place in this system, and is based on the work of several investigators. Liquid plus delta, delta, delta plus gamma and liquid plus gamma fields are drawn from Gayler's data,⁴ while the remaining fields, indicating the changes in the solid state from the data of Walters, Wells and co-workers.⁴

The results obtained by Walters and Wells concerning the changes in the solid state of the manganese-rich series of alloys are in much closer agreement with the

Fig. 1—Iron-Manganese Constitution Diagram.

Some specific information is still lacking, such as the limit of solid solubility for manganese in alpha iron.

Phases in the Iron-Manganese System—The characteristics of various phases that are found in practically carbonless iron-manganese alloys are given below. The regions occupied by such phases are clearly indicated in Fig. 1.

Delta—The delta iron-manganese solid solution has body-centered cubic atomic arrangement and is most probably of the replacement type.⁴

Gamma—The gamma iron-manganese solid solution has face-centered cubic lattice arrangement. The volume of the unit cell is increased with an increase in manganese concentration.⁵

Alpha—The alpha iron-manganese solid solution has body-centered cubic atomic arrangement, similar to that of delta iron-manganese solid solution. As in the

*Prof. of Metallurgy, Carnegie Institute of Technology, Pittsburgh, and Associate Director of Research, Allegheny-Ludlum Steel Co., Brackenridge, Pa.

†Assistant Metallurgist, Bureau of Metallurgical Research, Carnegie Institute of Technology, Pittsburgh.

⁴Probably this and all other solid solutions mentioned are of the replacement type, since the size of the atoms for iron and manganese are nearly identical.

work of Ohman¹ than with that of Gayler. It may now be definitely stated that the principal fields of the diagram and the reactions taking place in the iron-manganese system are well established, with the exception, however, of the epsilon phase which is discussed later. There still may be some doubt as to the accuracy of determined limits of temperature and concentrations. For this reason the alpha-gamma transformation in Fig. 1, and also the transformations taking place in manganese-rich alloys are shown with broken lines above certain concentrations.

gamma phase, the volume of the unit cell increases with increase in manganese concentration.³

Epsilon—The epsilon phase was only recently discovered by Schmidt.⁴ The atomic arrangement in this phase is found to be hexagonal close-packed. Although sufficient evidence concerning the nature of this phase is not available at present, it is likely that it is a solid solution and not an intermetallic compound.

The question of stability of the epsilon phase (and consequently its place in the constitution diagram) presents a controversial point. Some of the investigators believe that it is not a stable phase and should be regarded as quite comparable to martensite of iron-carbon alloys.⁵ Since, however, the fact of its formation in iron-manganese alloys under certain conditions (Fig. 2) is definitely established, its existence should be recognized.

Dilatometric Evidence—Fig. 2 is based on dilatometric evidence. The formation of epsilon from gamma on cooling and of gamma from epsilon on heating is clearly indicated.

It is to be observed that the hysteresis associated with the gamma to epsilon and the epsilon to gamma transformations is much less pronounced than in the case of the gamma to alpha and alpha to gamma transformations.³ In fact, the low hysteresis associated with such a low temperature transformation and involving such high melting point constituents is rather striking; it might be considered as at least some evidence in favor of stability of the epsilon constituent within certain temperature limits. Once the epsilon is formed, it persists to below room temperature, as dilatometric evidence indicates.

Alpha manganese-iron solid solution possesses a complex lattice structure with 58 atoms in the unit cell, of body-centered cubic type and with 29 atoms in a group at each lattice point. In pure manganese the allotropic change (from alpha to beta manganese) occurs at 742°C. According to Ohman the addition of iron does not, at first, materially change the temperature of transformation.

Beta manganese-iron solid solution has also a complex structure, cubic with 20 atoms in the unit cell. In pure manganese this phase is present at temperatures above 742 and below 1191°C.

Gamma manganese-iron solid solution has also a complex structure, cubic with 20 atoms in the unit cell. In pure manganese this phase is present at temperatures above 742 and below 1191°C.

Gamma manganese-iron solid solution is believed to have a face-centered tetragonal atomic arrangement with 4 atoms in the unit cell. In pure manganese it forms at 1191 and exists up to the melting point of manganese (1245°C.).

Gamma iron and gamma manganese are believed by some to form a continuous series of solid solutions, but Ohman suggests another possibility. The experimental data of Ohman¹ in regard to this question is not conclusive. No X-ray or microscopic evidence has been published indicating the presence of gamma iron and gamma manganese existing together in a two phase region.

The conclusion of Ohman that a narrow two phase region (gamma iron plus gamma manganese) may exist is based only on the fact that his data suggested a cubic lattice up to approximately 70% manganese and a tetragonal one from 70-100% manganese. Gayler's conclusions are in agreement with those of Ohman.

Phases, Iron End of Diagram—At the iron end of the diagram and at temperatures above 500°C. the phase relationship is quite simple (Fig. 1). Upon further lowering of the temperature the relationship becomes more involved, mostly because of the appearance of the epsilon phase.

Fig. 2 reproduces the results of the dilatometric studies regarding the relationship between various phases at the iron end of the diagram.⁶ The dilatometric method of analysis is quite adaptable to this system because of the definite volume changes that accompany the phase transformations. The same dilatometric method is particularly useful for the study of the epsilon phase,⁶ since the latter is not as

Fig. 2—Formation of epsilon from gamma on cooling and of gamma from epsilon on heating.

⁶For detailed description of volume changes see reference 3, part IV.

yet identified by means of a microscope. It will be seen from Fig. 2 that the line representing the upper part of the alpha to gamma transformation on heating agrees very well with data by Ohman. Similarly, on cooling, the lower limit of gamma to alpha transformation is practically the same as in Fig. 1. The existence of hysteresis previously mentioned is quite obvious. In this respect iron-manganese alloys are quite similar to those of iron-nickel.

The regions are indicated in Fig. 2 wherein the epsilon phase co-exists with gamma. The curves outlining the indicated areas do not represent the limits of the double phase regions, but merely the temperatures of the end of transformation (epsilon to gamma on heating and gamma to epsilon on cooling) as determined by dilatometric analysis. The experimental data do not permit a definite statement as to the type of reaction governing the relationship between gamma and epsilon phases. In fact, as has already been mentioned, the epsilon phase is held by some to represent metastable condition, which of course would exclude its presence in the equilibrium phase diagram.

Although Fig. 2 is not a constitution diagram, and consequently gives no information in regard to either the composition or the amounts of phases present, it shows that the addition of manganese to iron results in the following tendencies: First, a lowering of the gamma to alpha and alpha to gamma transformations, the former being affected more rapidly than the latter; second, as more manganese is added, a marked tendency of the alloys towards the formation of epsilon along with alpha as a product of the partially decomposed gamma phase; and third, formation of epsilon alone as a decomposition product. At the same time the amount of undecomposed gamma phase increases with the increase in manganese content.

Generally, a 10% manganese-iron alloy will contain on cooling alpha (predominating), some epsilon, and some untransformed gamma; a 13% manganese alloy will contain considerable amounts of all three phases; a 16% manganese alloy probably a little of alpha and considerable amounts of epsilon, and untransformed gamma. Beyond this concentration, the decomposition product will be almost entirely epsilon, the amount of which decreases as further additions of manganese are made. When concentration of manganese reaches about 40%, the gamma to alpha transformation, according to available information, does not take place at all. At this and higher concentrations, up to about 50% manganese, and at all temperatures from solidus down, the alloys consist of only one phase, gamma iron. At elevated temperatures gamma iron changes imperceptibly into gamma manganese with practically uniform changes in atomic volume.¹ Ohman, however, found a break in the lattice dimensions when exploring a complete series of alloys from 100% iron to 100% manganese, and, on the strength of his findings, indicated a heterogeneous field extending to the solidus line, the area of which is shown in Fig. 1 by broken lines. The type of reaction pertaining to this part of the system is shown, on a larger scale, in the upper right-hand corner of Fig. 1.

Eutectoids—Alloys of high manganese concentration show the existence of two eutectoid reactions; one, taking place at about 1000°C., in which the phases involved are gamma iron, gamma manganese, and beta manganese, and two, occurring at approximately 735°C. between gamma iron, beta manganese, and alpha manganese. The results of recent investigations of these alloys, using metallographic and X-ray methods fully substantiate the existence of the second eutectoid reaction.

Effect of Quenching on Phases—High temperature phases are retained, by quenching, much more easily in alloys of high manganese content than in alloys high in iron. In fact, quenching low manganese, high iron binary alloys seems to accelerate rather than inhibit the transformation to the low temperature phases. Hence, the study of the various phases and their relationship under equilibrium conditions is quite difficult. It is clearly shown by the complex structures of the low manganese iron alloys, when attempts are made to preserve high temperature phases by quenching.²

Constitution of Iron-Molybdenum Alloys

By W. P. Sykes*

The most recent and complete reports on studies of this alloy system are those published by Sykes,^{1,4} Takei and Murakami,² and Arnfelt.³ The constitution diagram in Fig. 1 is drawn from the data included in these reports. As this diagram indicates, the system may be described as follows:

(a) By the addition of about 3% molybdenum the gamma form of iron is completely eliminated.

(b) The solidus and liquidus temperatures pass through a minimum of 1440°C. at about 36% molybdenum.

(c) At 1450°C. the alpha solid solution is formed by a peritectic reaction be-

Fig. 1—Iron-Molybdenum Constitution Diagram.

tween the iron-rich liquid and the solid epsilon phase (Fe_3Mo_2). Some 38% molybdenum is dissolved in alpha at 1450°C. The solubility decreases to about 5% Mo at 500°C.

(d) Epsilon (Fe_3Mo_2) decomposes upon heating above 1480°C. to form an iron-rich liquid and a solid phase, eta.

(e) The eta phase appears to have a maximum molybdenum content of about 63%. This corresponds to the composition of an intermetallic compound having the formula FeMo .

(f) The eta phase in cooling undergoes a eutectoid transformation at about 1180°C. (SQR) the products being Fe_3Mo_2 and a molybdenum-rich solid solution containing about 6% iron. When heated above 1540°C. the eta phase decomposes into an iron-rich liquid and a solid solution of molybdenum (delta) containing about 11% iron.

(g) The solid solubility of iron in molybdenum decreases from about 11% at 1540°C. to about 5% at room temperature.

Properties of Pure Iron-Molybdenum Alloys—

The Rockwell and Brinell hardness numbers of the iron-rich alloys increase continuously with the addition of molybdenum up to about 40% by weight of molybdenum. Pure iron as quenched from 1425°C. has a Brinell hardness of about 60. An alloy containing 40% of molybdenum quenched from the same temperature has a Brinell hardness of about 450.

Fig. 4—Rockwell hardness of iron-molybdenum alloys.

*General Electric Co., Incandescent Lamp Department, Cleveland Wire Works, Cleveland.

Compositions lying between 40 and 80% of molybdenum are composed largely of the intermetallic compounds and are glass-hard, but brittle. Compositions within the solid solutions ranges at either end of the system are markedly susceptible to precipitation hardening as shown by Fig. 2. Those alloys containing about 20% molybdenum will develop a Brinell hardness of 500-550 by aging at 625°C. for 20 hr. after having been quenched from 1400°C. The hardness so developed will persist over a long period at temperatures up to 650°C.

Due to their normal coarse grained structure, however, these alloys are relatively brittle and consequently, in their present stage of development, have a decidedly limited field of application.

Constitution of Iron-Nickel Alloys

By Paul D. Merica*

The structure and equilibrium of the binary iron-nickel alloys have engaged the attention and interest of metallographers from the earliest days of the science when Osmond¹ presented the first constitution diagram of this series. Exhibiting a marked case of temperature hysteresis of transformation change in the alloys containing up to 34% nickel, and a curious anomaly in magnetic and elastic behavior of the alloys containing between 30 and 78% nickel, it is not strange that this series should have been the subject of so much study and discussion through the intervening years. Even today there are many questions regarding the iron-nickel equilibrium that are far from being solved or clearly understood.

The diagram reproduced in Fig. 1 is a composite based upon the work of most of those cited in the references, but chiefly: Hanson and Hanson²⁷ (transformations); Hanson and Freeman²⁸ (liquidus and delta region); and Honda and Miura²⁹ (irreversible transformations).

The equilibrium above 900°C. is clear. The temperature interval of freezing is not known with accuracy, but it is small. The freezing point displays a flat minimum at above 65% nickel.

In the solid state the alloys exist in three solid solution phases as follows:

Delta—Body-centered cubic lattice; parameter similar to that of alpha; exists within the field a c b.

Gamma—Face-centered cubic lattice; parameter varies nonadditively over that of nickel 3.517×10^{-8} cm. to 3.588×10^{-8} cm. at 39 atomic per cent of nickel, then decreasing to 3.575×10^{-8} cm. at 28.6 atomic per cent of nickel; exists at all temperatures beyond 34.4% nickel, at temperatures above e f for lower nickel contents and occasionally within area e f h i.

Alpha—Body-centered cubic lattice; parameter varies nonadditively from that of iron (2.86×10^{-8} cm.) to 2.875×10^{-8} for 32% nickel-iron; exists below e i and occasionally within area e f h i.

The delta and alpha phases are

Fig. 1—Iron-Nickel Constitution Diagram.

similar in all respects and should be regarded as the same phase with separated temperature ranges of stability.

Below 34.4% nickel the γ phase, upon cooling, suffers a transformation to the α phase, and because of the marked temperature lag between cooling and heating this has been called the "irreversible" transformation, and the alloys, the "irreversible" steels. Due to the marked temperature hysteresis of this transformation the true or equilibrium temperature position is not known. It is indicated on the diagram by the two temperature ranges actually observed on slow cooling and on slow heating.

The opinion is that these two temperature ranges (e f g and e h i) represent in reality one range of heterogeneous equilibrium, which lies somewhere between the two and which is the equilibrium range of the transformation and of the stable existence of both the γ and the α phases. That there is such an equilibrium temperature range of duplex phase structure is evident from a consideration of meteor structure. Below 780°C. the two phases γ and α are distinguished by the fact that

*Vice-Pres., International Nickel Co., Inc., New York.

the former is para, while the latter is ferromagnetic. The magnetic method has been widely used as a means of identifying the two. The line MN represents the temperature of the A_2 magnetic transformation, which is known only approximately.

Beyond 34.4% nickel the alloys suffer a magnetic transformation shown on the diagram by the line 1 k, but it is the present opinion that this does not correspond to a phase transformation. The chief evidence for this point of view is that of X-ray analysis which has demonstrated that there is no change in lattice type in passing through the transformation 1 k, and no discontinuous change in lattice parameter. The evidence therefore seems to support the view that whereas the "irreversible" transformation is a true phase transformation, definite and clear, the "reversible" one is associated with changes within the atom or perhaps within a small group of atoms²³ which does not affect primarily the lattice organization and is hence not a true phase transformation.

This transformation is thus similar to that of iron at A_2 and to that of nickel. In consequence of their reversible transformation, these alloys have been called the "reversible" nickel steels or ferronickels.

The reversible transformation also proceeds in the alloys of lower nickel content insofar as they contain the γ phase as indicated on the diagram. Alloys having between 26 and 34% nickel may therefore undergo either the "reversible" or the "irreversible" or both transformations, depending on their past thermal history.

Between 30 and 78% nickel the magnetic transformation is the origin of the so-called "anomaly" of the "reversible" ferronickels. Associated with it are marked but apparently quite continuous changes in all physical properties, particularly density (dilatation or expansion) and elasticity. At 36% nickel there is such a pronounced arrest in the thermal expansion below the magnetic transformation that industrial use has been widely made of the alloy, under the name Invar.²⁴

The simple conception outlined above of the nickel-iron equilibrium below 900°C. is not shared by all authorities. The principal point of dispute is the nature of the "reversible" transformation.

Benedicks²⁵ believes that there is an actual phase change associated with the reversible transformation between 30 and 78% nickel, which explains the dilatation and contraction observed on aging the alloys showing the dilatation anomaly. Those who share this belief are inclined to suspect the existence of a eutectoid transformation: $\gamma \rightarrow \alpha$ plus magnetic γ' , which has been placed variously at 0°C. and 345°C., although no direct evidence of this transformation is available. In some iron-nickel meteors, structures have been observed strongly suggestive of eutectoid structure, but this is not necessarily adequate evidence of eutectoid transformation. Chevenard^{26, 27} believes that the reversible anomaly is associated with a molecular (but not a phase) transformation involving the formation and dissociation of the compound Fe_2Ni (34.4% nickel). He has pointed out the significance of the fact that it is at this composition that the irreversible transformation ends.

It is evident from this discussion that the irreversible alloys are subject to heat treatment in the same sense and in much the same manner as steel. The segregate of α phase resulting from its separation from γ resembles the structure and the mode of formation of martensite. These alloys are often called martensitic nickel steels, since they are fairly hard even after air or slow cooling.

The reversible alloys are not affected in the usual sense by heat treatment and are only moderately hard under all conditions.

Constitution of Iron-Nitrogen Alloys

By John T. Norton*

General—Iron and nitrogen combine over a limited range of compositions to form solid metallic alloys. The maximum nitrogen content which can be obtained is about 11% by weight. It must be understood that an equilibrium diagram cannot be set up for this system without resorting to 3 dimensions, because the stability of the various phases is profoundly influenced by the nitrogen pressure. With this limitation in mind, it will be possible to set up a constitution diagram which will represent to a certain extent the relations between the phases of this system.

Fig. 1—Sawyer's Iron-Nitrogen Diagram.

When iron is treated with nitrogen gas in its molecular form, it is possible to obtain alloys with only a fraction of 1% of nitrogen. Even with pressures of the order of 100 atmospheres, little increase in nitrogen content is found. However, by the use of dissociated ammonia gas, elementary or monatomic nitrogen is obtained with an effective

nitrogen pressure corresponding to a very high value; under these circumstances, it is possible to form compounds of much greater nitrogen content. In the formation of the phases containing nitrogen, the diffusion rate of the nitrogen plays an important part, particularly at the lower temperatures where this rate is low. Consequently, in order to obtain a uniform distribution of nitrogen it is necessary to use samples having a very small cross section, such as powder, wire, or thin sheet, so that the composition will be the same in every part of the sample.

Iron-Nitrogen Constitution Diagrams—The first systematic attempts to set up a constitution diagram for this system seem to have been made independently by Sawyer¹ and Fry². These diagrams redrawn to the same scale are shown in Figs. 1 and 2.

Sawyer's Iron-Nitrogen Diagram—Sawyer employed microscopic and thermal analysis and his samples consisted of thin disks. The low nitrogen end of the diagram resembles that of the Fe-C system. He shows a solubility of nitrogen in alpha iron of about 0.03% by weight. The eutectoid

point occurs at about 1.8% nitrogen by weight and at a temperature of about 620°C. Sawyer's thermal analysis curves on heating indicated another eutectoid at a temperature of about 700°C. He concludes that the first eutectoid is formed from the alpha solid solution and the compound Fe₃N and the second between Fe₃N and Fe₂N. In the case of his nitrized disks, he decides that the outermost layer is Fe₂N, and that the two intermediate layers are Fe₃N and FeN.

Fry's Iron-Nitrogen Diagram—Fry's diagram is based on microscopic examination and magnetic measurements. The low nitrogen end is similar to that shown by Sawyer except that an increasing solubility with increasing temperature is indi-

Fig. 2—Fry's Iron-Nitrogen Diagram.

*Associate Professor of Metallurgy, Massachusetts Institute of Technology, Cambridge, Mass.

cated. He places the solubility limit of nitrogen in alpha iron as 0.015% at room temperature and about 0.5% at the eutectoid temperature of 580°C. The eutectoid composition is 1.5% nitrogen and is believed to be a eutectoid of the alpha solid solution and the compound Fe_3N . It has been named Braunitz. In the case of nitrized blocks, he observed two layers which he called Fe_3N and Fe_4N , but does not indicate the relations between these two compounds. Fry also mentions a phase resembling martensite in certain quenched samples.

Epstein's Iron-Nitrogen Diagram—The work of Epstein², which is really a modification and extension of the work of Sawyer and Fry, is based upon microscopic and thermal methods, together with some X-ray data (Fig. 3). The low nitrogen

Fig. 3—Epstein's Iron-Nitrogen Diagram.

portion of Fry's diagram is generally confirmed. Epstein finds the two series of thermal arrests on heating which were found by Sawyer but, because the microscope does not show the appearance of a eutectoid between the intermediate and inner layer of nitrides, he suggests that a peritectoid reaction takes place corresponding to the decomposition of Fe_4N , the innermost layer

of nitride. The intermediate layer of nitride corresponding to Fry's outer layer is called Fe_3N by Epstein and the thin outer layer is supposed to be Fe_2N . The X-ray data are not particularly conclusive.

X-Ray Determinations—Because of the possibility of nitrizing a fine powder to a substantially uniform nitrogen content, the X-ray diffraction method seems to be particularly suited to the study of the phases present in this system and their ranges of homogeneity. Two such investigations have been carried out independently by Eisenhut and Kaupp³ and by Hägg,⁴ which are generally in good agreement. Eisenhut and Kaupp (Fig. 4) place the maximum solubility of nitrogen in alpha iron as 0.42%. The eutectoid temperature is found to be 591°C. with a nitrogen content of 2.35%. The existence of two compounds is claimed by these workers. The first, which is stable over a narrow range in the vicinity of 5.9% of nitrogen, has a face-centered structure and is designated as Fe_3N . This phase, called gamma prime, has a cell size somewhat larger than, and evidently not continuous with, the gamma phase, which seems to be a simple solid solution of nitrogen in gamma iron. The second compound has its iron atoms arranged in a hexagonal close-packed structure and is stable at room temperature from about 8% of nitrogen up to the maximum limit of the system at 11.3%. This compound is designated as epsilon and believed to be Fe_2N . The compound Fe_3N is supposed to decompose at 650°C. into the gamma and epsilon phases. It is interesting to note that in certain samples quenched from the gamma range, a tetragonal structure is found which is very similar to the tetragonal martensite recently found in the iron-carbon system.

In the work of Hägg,⁴ the results are in substantial agreement with those of Eisenhut and Kaupp (Fig. 5). Hägg, however, finds indication of another phase, orthorhombic in structure beyond the epsilon phase. The high nitrogen limit of the epsilon phase

Fig. 4—Eisenhut and Kaupp's Iron-Nitrogen Diagram.

is about 11% nitrogen and the low nitrogen limit of the new phase is set at about 11.3% nitrogen. The theoretical composition of Fe_3N corresponds closely to the low nitrogen end of the orthorhombic phase.

Conclusion—A study of the work of these several investigators indicates the extreme difficulty of obtaining satisfactory working conditions. Nevertheless, certain aspects of the system appear quite definitely established. The alpha and gamma phases can be considered as true interstitial solid solutions of nitrogen in alpha and in gamma iron. The gamma prime phase seems to be definitely the compound Fe_3N and the nitrogen atoms have been located⁶ in the interstices of the close packed iron lattice. Undoubtedly there is a more definite relation than is shown

Fig. 5—Hägg's Iron-Nitrogen Diagram.

by the present diagrams between the gamma and the gamma prime phases, and this point merits further investigation.

nitrogen atoms are situated in the interstices of a lattice made up of iron atoms in what is essentially close packing. This undoubtedly depends upon the difference in size between the two kinds of atoms. It has been shown that practically all structures of this type have pronounced metallic properties. The X-ray evidence shows that definite compounds of the formulae Fe_3N and Fe_4N do not exist in this system.

Much work remains to be done to settle the details of this interesting system and a careful correlation of microscopic and X-ray evidence would be most helpful. The relations between the phases at the higher temperatures are still rather in doubt and a further study of the "nitrogen martensite" seems to have very promising possibilities because of its similarity to the analogous phase in the iron-carbon system.

Alloys of Iron and Oxygen

By Dr. C. H. Herty, Jr.*

Oxygen in Steel—Throughout this article the term "iron-oxygen alloys" is used to denote iron oxide (probably FeO) dissolved in iron. It is realized that the term may not be correct but it does express fairly satisfactorily the intended meaning.

The element oxygen is found alloyed in iron in varying amounts in all steels. Oxygen exists in steel either as iron oxide (FeO) in solid solution, in small amounts of manganese oxide (MnO) in solid solution, or as nonmetallic matter distributed throughout the steel. The oxygen in this nonmetallic matter generally consists of manganese oxide, silica, and alumina, as such or in various combinations. If special deoxidizers are used, there will generally be small amounts of resultant oxides present in the steel. Oxygen in these forms, however, is not to be considered as alloyed with the iron, as it is present as a nonmetallic inclusion.

In all steel making processes iron oxide is dissolved in the steel at some stage of the melting. In the basic electric furnace the amount present is at a minimum, whereas in the open hearth furnace and in the Bessemer converter there may be as high as 0.50-0.60% FeO dissolved in the liquid steel. Upon deoxidation the amount of iron oxide is reduced to an extent depending entirely upon the type and quantity of deoxidizers used.

From a commercial standpoint, alloys of iron and oxygen are of little importance. However, it is necessary to have a high oxygen content in steel to reduce the carbon to a low concentration. Oxygen is, therefore, of considerable importance in the manufacture of very low carbon steels where the desired factor is low carbon rather than high oxygen. In this respect, oxygen may be considered a necessary evil.

Fig. 1—Iron-Oxygen Alloys Constitution Diagram.

Constitutional Diagram of the Iron-Oxygen Alloys—Iron oxide lowers the melting point of iron approximately 10°C . when 0.94% FeO (0.21% oxygen) is present.¹ The solubility of iron oxide in iron is 0.94% at the melting point.² With increasing temperature above the melting point, the solubility increases and at 1600°C . the solubility is 1.37%. In commercial steels the iron oxide in liquid steel is less than

*Research Metallurgist, Bethlehem Steel Co., Bethlehem, Pa.

the amounts stated, so that the finished steel contains from traces to 0.30% FeO. The solid solubility of iron oxide in iron is about 0.22%¹—an estimate based on microscopic evidence, and therefore to be considered merely an approximation. In a recent investigation, Krings² found the solid solubility of oxygen in iron to be 0.11% (0.494% FeO) at 715°C.

The constitution diagram of the iron-oxygen alloys, as determined by Vogel and Martin³ from various sets of data, is shown in Fig. 1.

Hot Working of Iron-Oxygen Alloys—Alloys of iron and oxygen forge well at high temperatures. Austin⁴ found that the alloys were difficult to work in the neighborhood of 900°C., but this was not confirmed by other investigators. Cain⁵ has found that oxygen in the presence of considerable amounts of sulphur causes steel to be red short, but that if the sulphur content is very low the steel is not red short up to fairly high oxygen contents. Tritton and Hanson¹ and Bureau of Mines investigators⁶ found no difficulty in hot working iron-oxygen alloys, and in both these cases the sulphur content was very low—below 0.010%. Austin gives no sulphur values for his alloys, and it is possible that the red shortness might have been due to a combination of oxygen and sulphur.

Effect of Iron-Oxide on the Physical Properties of Steel—Iron-oxygen alloys, according to Austin,⁴ are fairly resistant to corrosion in air, being better than mild steel, but they are more easily corroded in water and in weak acid than mild steel or wrought iron. Austin found that the 900°C. critical point was lowered slightly, but this was not checked by the work of Tritton and Hanson, who found no change in critical points.

The iron-oxygen alloys are brittle under impact testing.^{1, 2} The hardness increases slightly with increasing oxygen content^{2, 4} and the ductility decreases with increasing oxygen content.¹ Very high oxygen contents make iron cold short.¹ The electrical resistivity of iron is increased considerably by oxygen²; apparently this increase is due to the FeO in solid solution as the resistivity is unchanged over a considerable range of oxygen contents above this solid solubility limit.

The ultimate strength of iron is not affected by the oxygen content, but the elastic limit is lower than reported values for pure iron.²

According to Yensen and Ziegler,⁶ oxygen has a great effect on the magnetic properties of iron. Yensen⁷ states that high silicon steels used for magnetic purposes probably owe their excellent properties to the extremely low oxygen content rather than to the high silicon content. The age hardening of steel is increased by increasing its oxygen content.

Iron-oxygen alloys when carburized show structures in which the cementite is always massive and very little pearlite is present, when observed under the conditions of the McQuaid-Ehn test.⁸

Constitution of Iron-Phosphorus Alloys*

By Louis Jordan†

The constitution diagram for iron-phosphorus alloys has been investigated up to only 30% phosphorus. Fig. 1 is the diagram as given by Haughton⁴. In its general form, this diagram agrees rather well with that portion of the diagram above 800°C. and up to 21% phosphorus, given by Konstantinow³. Konstantinow, however, indicated no field of gamma solid solution. Stead's¹ still earlier classification of iron-phosphorus alloys is consistent with Haughton's diagram. Saklatwalla's² constitutional diagram appears to be in error in several respects.

The iron-phosphorus liquidus falls from the melting point of iron to a eutectic of the alpha solid solution with Fe_3P at 1050°C. and 10.2% phosphorus. It then rises to a maximum of 1370°C. at 21.7% phosphorus, which is the composition of Fe_2P .

Fig. 1—Iron-Phosphorus Constitution Diagram (Haughton).

narrow two¹ phase field (represented in Fig. 1, however, as a single line).

Magnetically determined heating and cooling curves show the A_2 transformation in all alloys up to 13% phosphorus and a second magnetic point at 420°C., which is attributed to a transformation in Fe_3P similar to the A_0 in Fe_3C . Consequently this magnetic point at 420°C. is indicated in the diagram as continuing to the composition Fe_2P .

Hägg¹⁰ from X-ray analyses has assigned to the compound Fe_3P a body-centered tetragonal lattice and to Fe_2P a hexagonal lattice of the dimensions $a = 5.852 \text{ \AA}$ and $c = 3.453 \text{ \AA}$. He also found some evidence indicating the existence of FeP . Friauf¹¹ confirmed Hägg's results for the structure and lattice dimensions of Fe_2P . Two higher phosphides, FeP and FeP_2 , were prepared by Franke, Meisel, and Juza¹². Meisel¹³ determined lattice constants for FeP_2 . Roth, Meichsner and Richter¹⁴ have given heats of formation for Fe_3P , FeP , and FeP_2 .

Köster¹⁷ observed precipitation hardening in iron-phosphorus alloys containing over 1.2% P when quenched from 1000°C and reheated to 450-600°C.

*Published with the approval of the Director, National Bureau of Standards, Washington, D. C.

†Assistant Sec., American Institute of Mining and Metallurgical Engineers, New York.

During this rise the liquidus curve breaks at the peritectic temperature, 1166°C., and at a phosphorus content slightly below 15.6%, which is the compound Fe_3P . From the maximum of 1370°C. the liquidus again falls to a second eutectic at approximately 27% phosphorus and 1262°C., which is a eutectic between Fe_2P and a constituent as yet unidentified.

Haughton determined the limits of solid solubility of phosphorus in iron between the melting point of iron and the eutectic line at 1050°C. by heat treatment and microscopic examination of the specimens, and also from the eutectic line down to 600°C. by both metallographic examination and thermal analysis. The solubility of phosphorus at the eutectic temperature is 2.8% and at the A_2 point is 1.1% (A_2 is at 745°C. in a 1.1% phosphorus alloy).

The solution of phosphorus in iron rapidly lowers the A_2 transformation and raises the A_3 . The two lines join at about 1050°C. and 0.5% phosphorus which gives an enclosed field of gamma solid solution. The boundary between the fields of gamma solid solution and nonmagnetic alpha solid solution is a

Phosphorus as a Steel Alloying Element—Phosphorus has recently been recognized as a useful alloying element in certain steels.²¹ It raises the yield strength and improves the resistance to atmospheric corrosion in low-carbon, low-alloy steels.²²

Ferrophosphorus—Ferrophosphorus has some use as an addition to certain open hearth steels which are to be rolled to sheets, particularly for light gages. A small amount of phosphorus in the steel tends to prevent sticking of the sheets. Ferrophosphorus also may be added to a cupola charge when the pig iron is too low in phosphorus to meet the casting requirements. Two grades of the alloy are made^{12, 13, 14}, a 17-19% alloy and a 23-25% alloy. The latter is an electric furnace product while the former may be produced in the blast furnace.

The Constitution of Iron-Silicon Alloys

By Bradley Stoughton* and Earl S. Greiner**

Since the publication of the initial constitutional diagram of iron-silicon alloys by Guertler and Tammann,¹ in 1905, a number of investigators have studied this system and proposed revised constitutional diagrams. The literature relating to these investigations prior to 1933, has been critically reviewed in an Alloys of Iron Research Monograph² and a constitutional diagram of the iron-silicon system proposed. The portion of this diagram relating to alloys containing from 14-33.4% silicon has been modified in accordance with the results of a later investigation by Jette and Greiner.³ The revised diagram is shown in Fig. 1. The parts of this diagram which have not been definitely established are designated by asterisks.

The Iron-Rich Field—As shown in Fig. 1, silicon raises the A_1 transformation and lowers the A_2 transformation of iron. This results in a closed gamma loop having a limit at 2.2% silicon at 1170°C.⁴

Fig. 1—The iron-silicon constitution diagram.

temperatures below 800°C., exhibits a discontinuity at about 4.7% silicon (9 atomic per cent) as shown in Fig. 2, and have advanced two hypotheses as possible explanations of their data in addition to the following generalizations:

"1. In the range between 0 and approximately 6 atomic per cent silicon (0-3.1 weight per cent) completely homogenized alloys should have properties that vary regularly in a way that would be expected of a series of solid solutions.

"2. In the region of 9 atomic per cent silicon (4.7 weight per cent), or perhaps between 6 and 9 atomic per cent, irregular behavior may be expected.

"3. In the range above 9 atomic per cent silicon, regular variation in the properties should again be expected up to 25 atomic per cent, but the absolute values of the quantities measured will probably indicate that the alloy is less 'typically metallic' as the composition approaches Fe_3Si .† (Since there is no conclusive evidence that Fe_3Si exists as a compound, it is simply regarded as a distinguishing point in the solid solution.)"

The Remainder of the System—The diagram shown in Fig. 1 indicates that several intermediate phases exist in the alloys containing more than 15% silicon. These phases are as follows:

*Dean, Engineering College, Lehigh University, Bethlehem, Pa.

**Metallurgist, Bell Telephone Laboratories, New York.

†14.4% Si.

The solubility of silicon in alpha iron⁴ (Fig. 1) is 15.2% at 600°C., increases to 20.4% at 1030°C. and decreases to 18.5% at 1200°C. The solubility limit for temperatures above 1030°C. is uncertain due to disagreements in the available experimental data, and has not been determined for temperatures below 600°C. The discontinuities in the solid solubility curve, resulting from phase transformations, occur at 16.6% silicon at 825°C. and 20.4% silicon at 1030°C.

By an X-ray investigation of the iron-rich iron-silicon alloys, Jette and Greiner³ found that the curve of lattice constant (a_0) versus atomic per cent silicon, for

Designation	Wt. % Silicon	Corresponding Chemical Formula	Structure
Eta	25.1	Fe_2Si_3	(Unknown)
Epsilon	33.4	FeSi	Cubic ^a
Zeta	53.5-56.5	Tetragonal ^a

The eta phase (Fe_2Si_3), formed by a peritectoid transformation, is stable between 825 and 1030°C. However, the transformations occurring at these respective temperatures are sluggish. As a result, the eta phase may occur in these alloys below 825°C. or above 1030°C. if equilibrium has not been attained. The epsilon phase (FeSi), and the zeta phase, formed directly from the respective liquids on cooling, are

reported by Haughton and Becker⁷ to be stable at all temperatures to 0°C. Phragmén^{8, 9} has shown the zeta phase to have a tetragonal structure corresponding to the compound FeSi_2 (50.1% silicon), and considers the compound to have some of the iron atoms in the lattice replaced by silicon atoms, in order to form a stable phase. This explains the results obtained by Haughton and Becker,⁷ who found the homogeneous zeta phase extends from 53.5-56.5% silicon.

The solubility of iron in silicon is shown in Fig. 1 as being very small, which is in accordance with the results of Phragmén,⁸ and of Haughton and Becker.⁷ Murakami¹⁰ however, has reported a solubility of 4% iron in silicon.

Magnetic Transformations—According to Haughton and Becker,⁷ silicon

Fig. 2—Relation between lattice constant (a_0) and composition of iron-silicon alloys (Jette and Greiner).

lowers the alpha phase magnetic transformation (A_2) to 490°C. at 14.5% silicon, while further additions to 25% silicon do not change the transformation temperature. Murakami¹⁰ reported the alpha phase magnetic transformation at 450°C. in alloys containing from 16-30% silicon. Since Jette and Greiner⁴ have shown the alpha phase to be stable below 825°C. in the alloys containing from approximately 15-33% silicon, the magnetic transformation should occur in the alloys containing up to approximately 33% silicon, as shown in Fig. 1.

A magnetic transformation at 90°C. in the alloys containing from 16-30% silicon, was reported by Murakami.¹⁰ Later, Haughton and Becker⁷ found the temperature of this magnetic change to be 82°C. This transformation has been associated with the eta phase (Fe_2Si_3), but since this phase has been found to be unstable below 825°C., the magnetic transformation at 82 or 90°C. probably would not have been observed if the alloys had been in equilibrium.

Constitution of Iron-Sulphur Alloys

By G. F. Comstock*

The elements iron and sulphur form a compound FeS which contains 36.5% sulphur. Since for practical consideration in the metallurgy or metallography of iron and steel it is unnecessary to deal with alloys of higher sulphur content, this discussion will be confined to the alloys of iron and iron sulphide (FeS).

Nearly all authorities seem to be agreed that the system Fe-FeS is a simple eutectiferous one, and there is fairly general agreement in regard to the complete miscibility in the molten state. The constitution diagram has been determined by Friedrich,¹ by Loebe and Becker,² and more recently by Kozo Miyazaki,³ who took special precautions to avoid contamination by oxide. These diagrams agree closely. Starting with the freezing point of pure iron at 1530°C., the liquidus descends in an irregular curve to the eutectic at 985°C., then rises to the freezing point of FeS at 1190°C. The form of the liquidus curve may be reproduced quite closely with the following data, taken from Miyazaki's paper:

Constitution Diagram for Iron-Sulphur Alloys (Miyazaki).

With 20.9% FeS, the liquidus is at 1404°C.; with 61.34% FeS, it is at 1295°C.; the eutectic contains 83% FeS; and with 98.63% FeS the liquidus is at 1183°C.

The shape of the liquidus curve given by Benedicks and Löfquist⁴ is similar, but they state that the eutectic contains 30.9% sulphur, or 84.6% FeS. Sauveur⁵ states that this eutectic contains 85% FeS and melts at 950°C. McCance has given the eutectic temperature as 980°C. Friedrich showed the eutectic to contain 85% FeS and to melt at 983°C., and the melting point of FeS at 1171°C. Shibata found the melting point of FeS to be 1163°C. within 4° plus or minus,⁶ instead of 1190°C., according to Benedicks and Löfquist. However, these values

are in fair agreement, and probably Miyazaki's determinations can be accepted as practically correct.

In regard to the solubility of sulphur or FeS in solid iron, the information available is not definite. By electrical resistance measurements Miyazaki showed that the solubility must be less than 0.5% FeS, and from microscopic observations, he concluded that it was "practically zero at ordinary temperature." Benedicks and Löfquist state that "the solubility of sulphur in solid iron may be estimated at about 0.015-0.020% sulphur," and give good authority for this estimate in their recent book.⁶ The solubility probably increases somewhat with rise in temperature. Wohrman agrees that only about 0.05% FeS is held in solid solution by pure iron at atmospheric temperature. Some investigators seem to have found a slight lowering of the critical points of iron due to the presence of sulphur, but in general this effect has been inappreciable.

Iron sulphide (FeS) is easily recognized in polished sections of iron or steel by its bright yellow color, and its property of being readily attacked by boiling alkaline sodium picrate. Cementite, also darkened by this reagent, is much harder and paler in color, and could hardly be confused with the sulphide. The Fe-FeS eutectic structure has not been observed with the microscope, probably because (according to Wohrman) the components coagulate readily in the presence of excess iron.

The presence of carbon and manganese, as in commercial steels and cast iron, or of oxygen as in ingot iron, has of course an important influence on the equilibrium relations of iron and sulphur. These ternary alloys however are not included in the present discussion.

⁴A. Sauveur's Metallography and Heat Treatment of Iron and Steel, Third Edition, 1926.

⁵Kinzoku no Kenkyu, v. 3, p. 403.

⁶Benedicks and Löfquist, Nonmetallic Inclusions in Iron and Steel (Chapman and Hall), 1930, p. 13-15.

It is evident that our knowledge of this system is satisfactory only in the general outline, but that many details regarding the equilibrium relations in it are in need of further investigation. Indeed, the entire diagram should be redetermined with alloy specimens at least approaching modern standards of purity.

Constitution of Iron-Tungsten Alloys

By W. P. Sykes*

The constitution diagram of the binary iron-tungsten system is given in Fig. 1. The data used in drawing this diagram were taken from reports of Honda and Murakami,¹ Sykes,^{2,3} Arnfelt,⁴ and Chartkoff and Sykes.⁴ As shown by the diagram, the system may be described as follows:

Fig. 1—Iron-Tungsten Constitution Diagram.

(a) With the addition of about 6% of tungsten the gamma form of iron is completely eliminated.

(b) The solidus and liquidus temperatures pass through a minimum of 1525°C. at a composition of about 15% tungsten.

(c) The alpha solid solution is formed at 1540°C. by a peritectic reaction between the iron-rich liquid and the solid epsilon phase (Fe_3W). At 1540°C. about 32% tungsten is dissolved in solid iron and the cube edge of the iron lattice has been increased about 1%. The solid solubility of tungsten in iron decreases to about 6% at 500°C.

(d) Upon heating to about 1640°C. the epsilon phase (Fe_3W) decomposes to form an iron-rich liquid and a tungsten-rich solid, delta. The latter dissolves about 0.8% iron with a slight contraction of the tungsten lattice.

(e) A second intermetallic phase, beta, corresponding to the formula Fe_2W (62% tungsten) was first identified by Arnfelt. This appears to be formed* by a peritectoid reaction at about 1040°C.

As shown in Fig. 2, the hardness of the iron-rich alloys increases continuously with the addition of tungsten up to about 50% tungsten. Compositions lying between 50 and 90% tungsten are rendered

Fig. 2—Hardness of iron-tungsten alloys.

*General Electric Co., Incandescent Lamp Department, Cleveland Wire Works, Cleveland.

especially brittle by the presence of a large amount of the intermetallic compound Fe_3W_2 .

The iron-rich solid solutions containing more than 10% tungsten are susceptible to precipitation hardening, as shown by curve 2 in Fig. 2. An alloy containing 30% tungsten when quenched from 1500°C. has a Brinell hardness of about 200 as a single phase solid solution. By reheating at 700°C. for a period of 5 hr. the Brinell number is increased to about 550.

The tensile strength of these alloys is increased by aging, as is the hardness. A decrease in ductility accompanies the increase in tensile strength.

Alloys containing as much as 20% tungsten can be forged, rolled, and drawn at temperatures from 700-800°C. As formed by sintering or casting, the iron-rich alloys containing more than 5% tungsten tend to have a coarse grain structure which can be eliminated only by mechanical working.

Constitution of Iron-Vanadium Alloys

By Jerome Strauss*

In 1908 Vogel and Tammann² published the results of the first systematic study of the iron-vanadium system. They determined, however, only the liquidus and solidus lines, reporting no transformations in the solid state; part of this omission was obviously due to their failure to examine any alloys containing less than 10% vanadium. More recent investigations have not significantly altered the results reported at that date. By metallographic examination Oya³ confirmed findings that in the light of recent general investigation must obviously be correct, namely, that the isomorphous metals alpha iron and vanadium, being both of body-centered cubic structure, form a continuous series of solid solutions. Wever and Jellinghaus¹¹ studied the melting ranges of a series of alloys containing up to about 70% vanadium. With above 10% vanadium these alloys were not of high purity, containing 0.03-0.14% carbon and 0.16-2.01% silicon. At the same time the alloys of Vogel and Tammann were also not of high purity. Furthermore, the melting point of vanadium is not known with precision, having been placed variously between 1680 and 1750°C. The liquidus and solidus curves of Fig. 1 are therefore a compromise between the values on low vanadium alloys of Vogel and Tammann,² those on the purer alloys of Wever and Jellinghaus¹¹ and the melting point determination of most probable reliability, namely, the 1700°C. by Marden and Rich.⁷ The minimum solidification temperature is taken from Wever and Jellinghaus¹¹ at 31% vanadium and 1468°C., but the correct temperature may be slightly higher.

Putz¹ and Portevin⁴ both observed an increase in the temperature of the gamma to alpha transformation on the addition of vanadium to low carbon steels (0.1 and 0.2% carbon respectively) and Maurer who first proclaimed the existence of the "gamma loop" also used carbon-containing alloys, with 0.04-0.09%. All were correct in their deductions although not establishing the alpha-gamma boundary for pure alloys. There is still much disagreement concerning this boundary. The values for the extreme limit of the gamma phase ranges from 1.1-2.5% vanadium^{5, 6, 11, 14}. In view of the pro-

Fig. 1—Iron-Vanadium Constitution Diagram.

found effect of impurities, notably carbon, upon the outline of this field¹⁵ and the reported impurities of some investigations and obvious though unreported impurities of others¹, the limit of the gamma phase is here placed at 1.0% vanadium with the extreme of the adjacent gamma plus alpha field at 1.1%. This places maximum weight upon the work of Wever and Jellinghaus, whose low vanadium alloys contained as maximum impurities 0.01% carbon, 0.07% silicon, and 0.03% aluminum.

On the occurrence of the magnetic transformation there is also disagreement. Oya³ reported a slow increase in temperature with increased vanadium content, especially in the lower concentrations, with a maximum of about 850°C. at 15%;

*Vice-Pres., Vanadium Corp. of America, Bridgeville, Pa.

†Description of the nature, appearance, and method of preparation of some of the materials employed by some investigators leads the author to question some of the statements of purity which are not supported by detailed analyses; this applies especially to the vanadium used.

This article was not revised for this edition.

then a slow decrease changing to a rapid decrease above 20% and reaching room temperature at about 35% vanadium. Wever and Jellinghaus¹¹ reported a similar slow increase of the magnetic change up to 785°C. at 1.4% vanadium, then remaining at about this temperature (790°C. maximum) up to 29.5%; above this amount their conclusions require checking due to the presence of another phase associated with or replacing the solid solution. Their curve was similar to that of Oya but reached room temperature at 58% vanadium. Vogel and Martin¹⁴ showed a rise from 768°C. to about 820° at 3% vanadium and stated that the increase continued up to a content noted in different parts of their paper at 25 and 32%. Edlund¹⁶ noted values differing not too greatly from those of Wever and Jellinghaus up to about 25% vanadium, but a slower decrease above this percentage and no magnetic change above about 43%; the precision of the work was such that his data are used here.

As noted above, Wever and Jellinghaus described a new phase. Osawa and Oya¹² had observed that the change in the lattice parameter of the alloys did not proceed from that of iron (2.852Å) to that of vanadium (3.004Å) in accordance with Vegard's addition law. The later investigations confirmed these findings and, as a result of combined metallographic, thermal, X-ray, and magnetic data, outlined the field of what they assumed to be an intermetallic compound corresponding to the formula FeV and capable of dissolving limited amounts of either iron or vanadium; marginal two phase fields were also described. The separation of the pure compound was placed at 1234°C. and 48% vanadium (47.7 by formula). The lattice type was not definitely identified but stated to be complex. As there has been no published work in confirmation of the existence of this phase, its boundaries are indicated by dotted lines in the present diagram. The central field is here designated as epsilon since it is a solid solution and not a compound of constant composition.

It is apparent from this description that although parts of the iron-vanadium constitutional diagram are qualitatively correct, more work is required for precise location of the lines and definite confirmation of the intermetallic compound.

Constitution of Iron-Carbon-Molybdenum Alloys*

The first attempt at complete determination of the iron-carbon-molybdenum system was made recently by Takesi Takei. This report represents a vast amount of experimental work. It is worthy of special note that this is probably the first time that the initial diagram of a ferrous ternary system is constructed in accordance with phase rule requirements. It is probable, then, that future contributions to this system will chiefly bring adjustments rather than effect radical changes.

In Fig. 1 is given the steel corner from the iron-carbon-molybdenum diagram. Although not given in Fig. 1, the phases in the complete diagram are identified as follows:

Phase	Explanation
α	Solution of Mo and C in α Fe
γ	Solution of Mo and C in γ Fe
c	Fe_3C (capable of dissolving Mo, C and Fe)
ω	Double carbide of Fe and Mo
ϵ	Fe_3Mo_2 containing Fe and C in solution
η	FeMo containing Fe and C in solution
θ	Mo_2C (capable of dissolving Fe and Mo)
δ	Solution of Fe and C in Mo
ν	The melt

Isothermal sections show the nature of the ternary system for the iron-carbon-molybdenum alloys. At 800°C. the diagram discloses the presence of the γ phase and at 1200°C. a liquid phase is present.

The complete diagram becomes speculative at high molybdenum and carbon concentrations. Fortunately, the portion which has already been established with reasonable certainty is also the portion of greatest usefulness—for low molybdenum contents.

Although isothermal sections alone do not tell what happens to alloys as they are heated or cooled, the trends of the various boundaries may be inferred from an inspection of the diagrams. The sec-

Fig. 2—Isothermal diagrams for iron-carbon-molybdenum alloys with 2% molybdenum.

Iron-Carbon-Molybdenum Alloys—Twelve structural diagrams for the iron-carbon-molybdenum system up to 1.2% carbon and 6.0% molybdenum were established from

Fig. 1—Steel corner of the iron-carbon-molybdenum diagram.

tions of the diagram at 2, 4 and 10% molybdenum are shown in Fig. 2, 3 and 4. The complex nature of the system is caused principally by the appearance of the ω or double carbide phase. While these section diagrams of constant molybdenum content cannot be used to estimate relative proportions and compositions of phases present, they are useful in indicating the number and nature of phases present at any temperature and composition.

Structural Diagrams for
ams for the iron-carbon-
um were established from

*Abstracted from the literature by the editorial staff.

microscopic and hardness examinations of 41 alloys. The results of this study were reported in a paper by Blanchard, Parke and Herzog before the A.S.M., October, 1938, and published in the Transactions of the A.S.M. in 1939. The analysis range of the alloys used in this study follows: C 0.05-1.33%, Mo 0.04-6.34%, Mn 0.11-0.31%, Si 0.07-0.33%. All compositions were low in S and P.

Alloys were melted in a 30 lb. high frequency induction furnace. No aluminum additions were made. The ingots were forged into 1 in. round bars and ground to $\frac{1}{8}$ in. round. Specimens $1\frac{1}{2}$ in. long were held at temperature for 1 hr. Hardness measurements and microscopic observations were made at a point equidistant from the center and the surface of the specimen. In these diagrams the constituents are designated as follows:

C	Carbide
P	Pearlite
M	Martensite
ω	Double Carbide
W	Widmanstätten
B	Bainite
F	Ferrite

The diagrams in Fig. 5, 6, 7 and 8 show the structural compositions for alloys, water quenched from 1550 and 1650°F. and normalized at the same temperatures.

Fig. 3—Same as Fig. 2, but with 4% molybdenum.

Constitution of Iron-Chromium-Carbon Alloys

By Walter Crafts*

Chromium-Carbon System—The chromium-carbon system has received attention since as early as 1856 when Sainte-Claire Deville investigated the reduction of chromium oxide by carbon. Since that time many investigations have been carried on for the purpose of establishing an equilibrium diagram for the system. A diagram was proposed by Hatsuta¹ and is probably the most accurate representation of equilibrium conditions available. The carbides Cr_7C_3 , Cr_3C_2 , Cr_7C_3 , are well established, but existence of CrC has not been verified. Recent work by Westgren² has shown that the carbide Cr_7C_3 is really Cr_{23}C_6 . The eutectic between chromium and Cr_7C_3 is placed at 1485°C . and 3.7% carbon.

According to X-ray analysis the carbide Cr_7C_3 is face-centered cubic, Cr_3C_2 is trigonal and Cr_7C_3 is orthorhombic. With reference to the ternary system iron-chromium-carbon, only Cr_7C_3 and Cr_3C_2 need be considered, since Cr_7C_3 does not occur in any of the usual alloys.

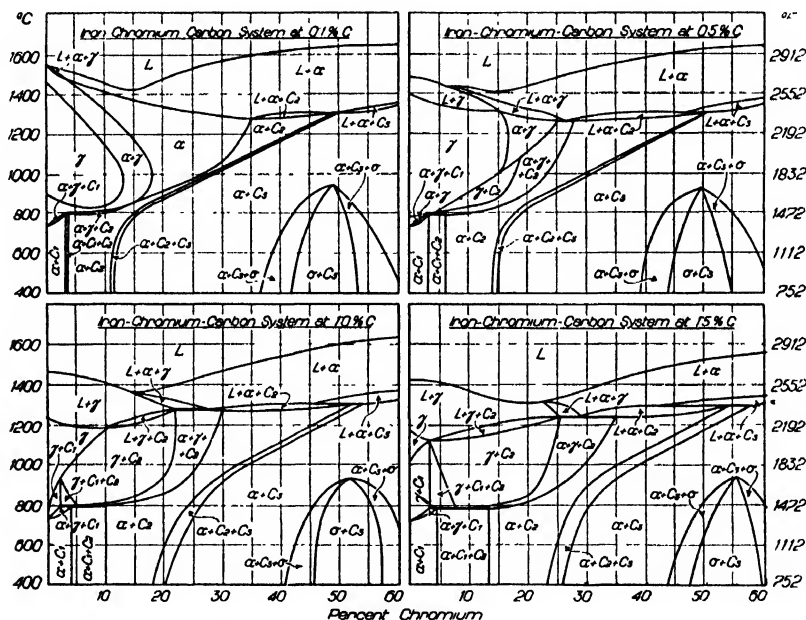

Fig. 1.—Iron-chromium-carbon system at 0.10, 0.5, 1.0, and 1.5% carbon.

Iron-Chromium-Carbon System—The system iron-chromium-carbon has been studied by many investigators, and sufficient data have been obtained to justify the construction of a ternary diagram for the iron-rich corner of the system. While some details of the contiguous binary systems are not certain, the general features of the partial system iron, iron-carbide, chromium-carbide, chromium are so well recognized that the diagrams taken chiefly from the investigations by Tofaute, Sponheuer, and Bennek³ and Tofaute, Küttner, and Büttinghaus⁴ may be considered satisfactory for practical interpretation of the behavior of the usual iron-chromium-carbon alloys.

Sections at 0.1, 0.5, 1.0, and 1.5% carbon are given in Fig. 1. Fig. 2 shows the sections at constant chromium contents of 5, 12, 20, and 30%. An isothermal section of the iron-chromium-carbon diagram⁵ at temperatures of 1150°C . is given in Fig. 3.

The carbide phases designated as C_1 , C_2 , and C_3 in the diagrams have the following formulae and compositions:

*Union Carbide and Carbon Research Laboratories, Inc., Niagara Falls, N. Y.

C_1 — $(Fe,Cr)_3C$ —Iron carbide capable of dissolving up to about 15% chromium.
 C_2 — $(Cr,Fe)_7C_3$ —Chromium carbide capable of dissolving up to about 55% iron.
 C_3 — $(Cr,Fe)_4C$ —Chromium carbide capable of dissolving up to about 25% iron.

The other phases have been designated as follows:

L—Liquid
 X—Ferrite
 γ —Austenite
 σ —Sigma ($FeCr$)

Fig. 2—Iron-chromium-carbon system at 5, 12, 20, and 30% chromium.

The orthorhombic carbide $(Fe,Cr)_3C$ is found in only the lowest chromium steels, and as the chromium content is increased the trigonal carbide $(Cr,Fe)_7C_3$ makes its appearance. The presence of cubic carbide Cr_3C is dependent upon both the carbon and chromium contents. For example in low carbon steels it appears at about 10% chromium whereas with 3% carbon present it is found only in alloys containing more than about 35% chromium. It is fairly certain that $(Cr,Fe)_7C_3$ forms as a result of peritectic transformation, and the same is probably true of $(Cr,Fe)_3C$.

Four 4-phase equilibria exist in the iron-chromium-carbon system. Three of these are of the transition-plane type while the other is of the eutectic type. The ternary eutectic point lies close to the plane of the iron-carbon diagram. The nonvariant equilibrium of greatest practical importance is the one involving the phases alpha, gamma, $(Fe,Cr)_3C$ and $(Cr,Fe)_7C_3$, which exists at about 800°C. In view of the position of the co-ordinates for this quadrangle, namely 2.6% chromium and 0.05% carbon for the alpha corner and 2%

Fig. 3—Iron-chromium-carbon system at 1150°C.

which exists at about 800°C. In view of the position of the co-ordinates for this quadrangle, namely 2.6% chromium and 0.05% carbon for the alpha corner and 2%

chromium and 0.7% carbon for the gamma corner, it is possible for the chromium carbide, Cr_7C_3 , to appear in many steels containing more than 2% chromium.

The constitution of the alloys with less than about 2% chromium is not markedly different from that of iron-carbon alloys. With increasing chromium content, however, the single phase gamma region is shifted to lower carbon contents and disappears entirely at about 20% chromium. The temperature limits of the region are also restricted with increased chromium content. From a practical standpoint this means that higher heat treating temperatures must be used for those operations that depend upon transformation to and from the gamma phase.

The solubility of carbon in the alpha phase of iron-rich alloys at temperatures just below the freezing point increases slightly with increasing chromium content. The carbon content of the "eutectoid" is decreased by increasing the chromium content.

At chromium contents above about 40% it will be noted that the phase designated as "sigma" makes its appearance. It appears likely that this phase results from the allotropic transformation of a saturated alpha solid solution although it has been classed as a compound and assigned the formula FeCr . This phase is not stable at temperatures above 900°C . and in most cases is developed only after extended holding times in the temperature range of 600 - 1000°C .

Constitution of Iron-Manganese-Carbon Alloys

By C. Wells*

Historical—The iron-manganese-carbon diagram derived by Bain, Davenport, and Waring,¹ published in 1932, was the first to give reasonably complete data concerning the constitution of the industrially important ternary alloys in the solid state when brought approximately to equilibrium at various temperatures.

Fig. 1—A diagrammatic representation of the iron-manganese-carbon ternary diagram.

Between 1888, when Hadfield steel was discovered, and 1932 a number of investigations were conducted using various experimental methods for the purpose of determining the effect of heat treatments on the constitution of the ternary alloys

Fig. 2—2.5% manganese section of the ternary diagram for alloys of iron, manganese, and carbon.

*Metals Research Laboratory, Carnegie Institute of Technology, Pittsburgh.

of commercial purity.³ In general, however, this effort was concentrated on the high and low manganese steels of industrial importance, and the supposedly brittle alloys of intermediate manganese content were neglected. Furthermore, in only

Fig. 3—4.5% manganese section of the ternary diagram for alloys of iron, manganese, and carbon.

one or two of these investigations were the heat treatments prolonged sufficiently to bring the high manganese ternary alloys close to equilibrium. It is not surprising, therefore, that the rather uncertain diagram published by Guillet,⁴ showing

Fig. 4—7% manganese section of the ternary diagram for alloys of iron, manganese, and carbon.

simply the constitution of iron-manganese-carbon alloys after being forged and air cooled to room temperature, was the best available until the paper of Bain, Davenport, and Waring was published.

Although the diagram of Bain and his co-workers may not be considered en-

tirely satisfactory, because commercial rather than high purity alloys were used, this objection from a practical standpoint is not serious, since the broad aspects

Fig. 5—10% manganese section of the ternary diagram for alloys of iron, manganese, and carbon.

of the constitutional diagram have since been shown to remain the same. This is clear from a series of papers^{4, 5, 6}, which describe the constitution in the solid state

Fig. 6—13% manganese section of the ternary diagram for alloys of iron, manganese, and carbon.

of high purity iron-manganese-carbon alloys containing up to about 13% manganese and 1.5% carbon.

Iron-Manganese-Carbon Constitution Diagram—The diagrams published by E. C. Bain and co-authors and by F. M. Walters and co-authors were determined by examination under the microscope of quenched specimens, previously brought close to equilibrium at crucial temperatures. In the determination of the 2.5 and 4.5% manganese sections of the ternary diagram dilatometric studies also proved useful.

A comparison of the results using alloys of commercial purity with those

Fig. 7—0.2% carbon section of the ternary diagram for alloys of iron, manganese, and carbon.

Fig. 8—0.4% carbon section of the ternary diagram for alloys of iron, manganese, and carbon.

obtained using high purity alloys shows general agreement. For the purpose of a general understanding of the behavior of the ternary alloys as a whole, a diagrammatic representation of the ternary diagram is given in Fig. 1. The space indicated by ϵ ? is of doubtful significance because it is not known whether epsilon is a stable or transition constituent. At temperatures just above those indicated by the upper

Fig. 9—0.6% carbon section of the ternary diagram for alloys of iron, manganese, and carbon.

Fig. 10—0.8% carbon section of the ternary diagram for alloys of iron, manganese, and carbon.

surfaces only the gamma phase is stable. Below these the stable phases are as represented and occur between limits indicated by the limiting boundaries. The line between the upper two surfaces represents the upper eutectoid compositions and temperatures (723°C. and 0.80% carbon for pure iron-carbon alloys, and 600°C. and 0.30% carbon for 13% manganese ternary alloys). As alloys of suitable composi-

tions are cooled at an extremely slow rate from the gamma field (above ABC, Figs. 2-6) proeutectoid carbide separates between temperature limits indicated by CBE and proeutectoid alpha solid solution between limits indicated by ABD. Cooling further (below DBE) at a similarly slow rate results in a simultaneous precipita-

Fig. 11—1.0% carbon section of the ternary diagram for alloys of iron, manganese, and carbon.

Fig. 12—1.2% carbon section of the ternary diagram for alloys of iron, manganese, and carbon.

tion of alpha solid solution and carbide from the gamma solid solution giving a binary eutectoid of varying composition as the temperature is lowered, until temperatures represented by FG are reached, at which point the remaining gamma solid solution in the alloys is completely transformed into alpha solid solution + carbide.

Fig. 13—Curve showing the influence of manganese on the upper eutectoid temperature limit in alloys of eutectoid composition.

Fig. 14—Curve showing the influence of manganese on the carbon concentration in alloys of eutectoid composition.

Adding manganese to iron-carbon alloys makes possible the co-existence of three phases, alpha, gamma, and carbide, in equilibrium (field between DE and FG, Figs. 2-6).† As carbon is added to iron-manganese alloys of constant manganese content, the upper and lower temperature limits at which the three phases can exist in equilibrium are raised.*

†A discussion of the conditions which may give rise to the type of sectional diagram indicated in Figs. 2-6 is given in "Principles of Phase Diagrams," by J. S. Marsh¹², p. 134-146.

*When the carbide, gamma, and alpha phases co-exist in equilibrium, the components, carbon, manganese, and iron are so distributed that the concentration of the manganese and of the carbon is highest in the carbide, intermediate in the gamma, and lowest in the alpha phases. Due to this distribution of components in the phases, an increase in carbon in iron-manganese-carbon alloys of constant manganese content results in a decrease of manganese in the gamma in equilibrium with alpha and carbide phases at the upper and lower temperature limits of the eutectoid reaction and therefore in a raising of the upper and lower temperature limits of the three-phase zone.

The effect of manganese upon the temperature zones of stability for the phases in alloys of constant carbon content is indicated in Fig. 7-12.

The upper temperature limit of the eutectoid reaction as indicated by B (Fig. 2-6) is lowered with an increase of manganese in the ternary alloys (Fig. 13), and the carbon concentration in these ternary alloys of eutectoid composition is also lowered with increase of manganese (Fig. 14).

Bain and co-authors have indicated a small single alpha phase field in their sectional diagrams; but Walters and co-authors have preferred not to do this, because there are insufficient equilibrium data available to indicate the limits of this field with certainty. The single alpha phase field if indicated in the sectional diagrams (Fig. 2-6) would appear to the left of and above DF.

An epsilon phase field is not indicated in any of the diagrams, because there is much uncertainty regarding the stability* of epsilon, and because the knowledge of the phase relationships between epsilon and other phases is uncertain.

Since the sectional diagrams presented are neither binary nor pseudobinary diagrams, they give no indication of the proportions or compositions of two or more phases co-existing in equilibrium. Until such time that the chemical compositions of each phase in equilibrium with the other phases are known, only an incomplete knowledge of the portion of the ternary diagram studied is possible. At the present time little data of this kind are available.

Phases Present—Up to 13% manganese and 1.5% carbon no phases crystallographically different from those found in the binary iron-manganese and iron-carbon alloys have been observed.

Carbide—Iron-manganese carbide, (Fe, Mn)₃C, which occurs in the ternary alloys containing up to 13% manganese and 1.5% carbon has an orthorhombic structure⁸ similar to that of cementite in iron-carbon alloys, and contains about the same concentration of carbon as iron carbide. The concentration of manganese in the carbide occurring in these ternary alloys depends upon the concentration of manganese in the alloys.¹⁰ Under equilibrium conditions the percentage of manganese in the carbide is always much higher than that in the alloy, and in high manganese steels of the Hadfield type the carbide present may contain between 20 and 25% manganese, in which case there would be 1 atom of manganese to every 3 or 4 atoms of iron in the carbide. The analysis of carbide separated from alloys containing 1% carbon and 5-13% manganese is given by Arnold and Read¹¹ as approximately 7% carbon and 22% manganese (iron by difference). In ternary alloys of much higher manganese content other carbides (Mn, Fe)₃C, (Mn, Fe)₂C₃, and (Mn, Fe)₂C₅ may exist. This is evident from a comparison of the data of Westgren and Phragmén¹⁴ with those of Holmquist¹⁵ and Wells¹⁶ which show that the carbides of manganese (probably Mn₃C and Mn₂C₃) are very similar to those of chromium (Cr₃C and Cr₂C₃) in structure and dimensions.

Gamma Iron-Manganese-Carbon Solid Solution—In the gamma phase manganese atoms replace some of the iron atoms at the lattice points of the face-centered cubic gamma iron lattice while carbon atoms enter the interstices¹¹. Both manganese and carbon in solution in gamma iron increase the size of the unit cell.

Alpha Phase—This is an iron-manganese solid solution in which the solubility of carbon is quite low.¹² In this phase manganese atoms replace some of the iron atoms in the body-centered cubic alpha iron lattice and cause an increase in the size of the unit cell.

Epsilon Constituent—This constituent has a close-packed hexagonal crystal structure and occurs most readily in iron-manganese-carbon alloys containing high manganese and low carbon concentrations. The formation of epsilon in iron-manganese alloys containing very low carbon concentrations is described in this handbook. See chapter on "Constitution of Iron-Manganese Alloys."

Epsilon also forms from the gamma phase in high manganese steels of the Hadfield type during cooling after a heat treatment to precipitate most of the carbide from the gamma phase.

The Constitution of Iron-Nickel-Aluminum Alloys

By L. L. Wyman*

The iron-nickel-aluminum ternary system has only been partially explored, the work on this being done by Köster,¹ and more recently by Bradley and Taylor.² The room temperature plots of these two diagrams do not entirely conform to the best available information on the three binary systems involved, and need some modification in order to do so.

The Köster diagram consists essentially of the ranges of the alpha (Bcc) and gamma (Fcc) alloys, established by thermal, microscopic, and magnetic analyses.

Fig. 1—Liquidus surface of the iron-nickel-aluminum system.

Fig. 2—Elevations at various nickel contents in the iron corner of the iron-nickel-aluminum system.

The Bradley and Taylor diagram, while it incorporates essentially the same "two phase" area, shows that this range is made more complex by the formation of superlattices.

The work of other investigators has shown that the magnetic properties are related to the formation of superlattices rather than to the phase relationships, so that the Bradley and Taylor diagram, taken as confirmation of the Köster ternary, and the best knowledge of the binary systems, might be considered the nearest to the true construction which is known at present.

Fig. 1 shows the plot of the liquidus surface of the ternary system, as worked out by Köster, while Fig. 2 shows the elevation at various nickel contents, in the iron corner of the ternary system (Köster).

*Research Laboratory, General Electric Co., Schenectady.

Fig. 3 shows the room temperature plot of the ternary system constructed according to the best information, using the phase and magnetic limits established by Köster, and the superlattice fields according to Bradley and Taylor, having both conform to the most reliable binary systems as limits.

Fig. 3—Room temperature arrangement of the iron-nickel-aluminum system.

The nomenclature used is in conformity with the iron structures, alpha being body-centered cubic, and gamma being face-centered cubic.

Beginning in the iron-rich corner of the diagram it will be noted that the alpha Fe-Al alloys have two superstructures, the α_1 being of the Fe_3Al type, having iron atoms at the cube corners and iron and aluminum atoms alternating in the center positions in adjacent cubes, while the α_2 has the FeAl type of superlattice with iron atoms at the cube corners and aluminum atoms at the cube centers.

The shading lines in the alpha and gamma, alpha and α_2 , and theta, gamma and theta fields are in accordance with the Bradley and Taylor diagrams and are intended to show that the products of decomposition of any alloy having a composition represented as a point on these or similar lines would be represented by the phases corresponding to where these lines intersect the adjacent fields.

The nickel-rich ternary alloys have not been clearly established as yet, for Bradley and Taylor believe that the nickel-rich Al-Ni solid solution has a superlattice, while Alexander and Vaughan³ clearly reveal the presence of a new face-centered phase theta. Consequently this portion of the diagram does not conform to equilibrium relationships.

The interesting alloys in this system are the permanent magnet materials in the neighborhood of the compound Fe_2NiAl (29.7% Ni, 13.7% Al) which on proper cooling set up a superlattice, and give rise to remarkable magnetic properties.

The slow cooling of Fe_2NiAl places it in a two phase field made up of alpha, having its atoms at random, and the α_2 phase having a superlattice. The former also has a lattice spacing 0.3% less than the latter. Cooling the alloys in this range at the proper rate permits a portion of the above reaction to take place, but does not carry on to completion. This gives rise to a condition of immense strain, due to the differences in lattice size, to which Bradley and Taylor² attribute the high coercivity of these compositions.

The Iron-Nickel-Chromium System

By Edgar C. Bain* and Robert H. Aborn†

The ternary system iron-nickel-chromium is particularly interesting from the scientific standpoint in that it is relatively simple, and at the same time carries the reflection of phase shifts accompanying allotropy in one of its components, iron.

Fig. 1—Iron-Nickel Constitution Diagram.

At the outset it is obvious that iron, in one or the other of its allotropic states, forms a complete series of solid solutions with chromium and also with nickel. Thus ferrite, the alpha or delta iron solid solution, may carry only limited

amounts of nickel, but approach 100% chromium without any new phase appearing. Similarly austenite, the gamma iron solid solution, may carry only limited chromium, but approach 100% nickel. Thus, except for intermetallic compounds (and one does exist below about 1650°F.), the entire system must consist only of two phases (body- and face-centered cubic) which, however, will vary considerably as to composition range depending upon temperature. In spite of the fact that the words austenite and ferrite are usually applied only to relatively dilute solid solutions in the two forms of iron, it is nevertheless so convenient to extend the terms for the present

consideration, to higher concentrations of dissolved elements that this procedure will be adopted.

Fig. 3—Chromium-Nickel Constitution Diagram.

While there is little evidence that the chromium-rich ternary alloys have been explored, there is nevertheless a fair degree of probability that the phases at equilibrium in the entire system may be predicted now with considerable assurance; the character of the system in the iron or nickel-rich range permits of some reasonably valid inferences concerning the remainder of the system. Before the several phases in the three component alloys are considered it may be well to review the three binary equilibrium diagrams, Fe-Ni, Fe-Cr and Cr-Ni, as set forth in Fig. 1, 2 and 3.

Fig. 2—Iron-Chromium Constitution Diagram.

From various sources, a fairly accurate approximation of the melting temperatures of the binary systems have been assembled; with reference to the ternary alloys little is known, but commercial melting experience shows that the customary iron-chromium-nickel alloys melt at temperatures not much below the fusion temperatures of the binaries, especially in the iron-rich compositions. From this it may be inferred that in the three-dimensional phase diagram the solidus-

Fig. 8—Constitution of the iron-nickel-chromium system as developed by rapid cooling from the conditions of Fig. 5.

liquidus surfaces are fairly flat. With respect to the conditions in the solid state the knowledge is more abundant.

Fig. 4† shows the state of affairs as regards the constituent phases just below the solidification range. The high temperature alpha iron (delta iron) solid solutions make themselves felt by a strong sweep of the ferritic crystal structure into the iron-

nickel side of the diagram. Fig. 4 may be regarded as a plan view of the ternary diagram with the two phase (solid and liquid) regions removed.

As the temperature is lowered the distribution of phases is considerably altered, until within the temperature range approximately 1650-2370°F. (the exact temperature depending upon the composition) the gamma iron solid solution reaches its maximum extent, and, correspondingly, the purely ferritic family of alloys is reduced to its minimum extent. This is illustrated in

Fig. 9.—The effect upon constitution of (left) nickel in an 18% chromium alloy, and of chromium (right) upon an 8% nickel alloy.

Fig. 5. A plane section through the (solid) ternary constitution diagram at the 1650°F. temperature level is shown in Fig. 6. The iron-chromium compound (probably Fe-Cr) first appears at this level and thereby introduces some six new phase fields, owing to its binary and ternary equilibria with ferrite, austenite, and chromium-rich solid solution. A curious feature of the iron-rich corner is shown in enlarged detail in Fig. 6A. This is occasioned by the fact that the A_s transformation in purified iron is in the vicinity of 1670°F. and that small additions of either nickel or chromium then tend to stabilize austenite and thereby lower the A_s transformation to temperatures below 1650°F.

The compound, based upon the approximate composition Fe-Cr, forms only from compositions which are, at least in part, ferritic, and then relatively slowly, so that in rapidly cooled alloys it is never found. Its rate of formation is at a maximum only a few degrees below the maximum temperature at which it may exist at equilibrium.* The approximate iron-chromium composition range in which it may form is illustrated in Fig. 2, but it may form also in alloys carrying as much as approximately 30% nickel. (See Fig. 6 and 7). Apparently it may not form from ferrite richer in chromium than about 55%. Nickel slightly raises the maximum temperature of stability of the compound so that in the solid diagram its phase boundary is seemingly a mound rising to somewhat above 1650°F. at some 5% nickel and slightly under 50% chromium.

The compound itself is hard and brittle and nonmagnetic; its crystal structure has not been reported and the diffraction pattern is such as to suggest a complex crystal of low symmetry. When it is formed in an iron alloy of some 30% chromium after long periods at about 900°F. it is located in a thin intergranular

†The usual triangular portrayal of phase distribution at constant temperature for three components is employed here not only for single temperatures but also for certain qualified conditions over a temperature range. It should be borne in mind that only two independent variables are really possible of representation on a plane surface and that three component systems are really of such a nature since the concentration of any one component of the three is a function of the sum of the concentrations of the other two; that is, $100\% - A\% - B\% = C\%$. The triangle merely cuts off the unreal magnitudes of any two components at the 100% maximum.

It should be noted that all diagrams shown here are only approximate but they are drawn in such a way as to be consistent both with the available information and with thermodynamic considerations as expressed in the phase rule.

*It is, of course, nearly impossible to prove that the compound, based on FeCr would form in absolutely pure iron-chromium alloys, with or without nickel. Adcock is inclined toward the interpretation that the compound forms as a result of possible contamination. The present authors on the other hand believe that the large number of instances in which the compound has been observed warrants including it in the equilibrium system. One of them found this constituent formed throughout the whole of a 1 in. section of iron-chromium alloy prepared by melting pure electrolytic metals in vacuum and subsequently maintaining the metal at the most rapid transformation temperature, also in vacuum. It is suggested that Adcock use a temperature too low to develop the transformation in the compositions employed to an extent sufficient for detection.

network and extreme brittleness results. Some brittleness or loss of ductility appears in such compositions, however, before evidence of any precipitation of the compound exists.

At temperatures much below about 1290°F. the alloys carrying more than 15% nickel, or even less nickel if accompanied by perhaps 10% chromium, are unable to reach the equilibrium state in any ordinary time interval; instead they tend to

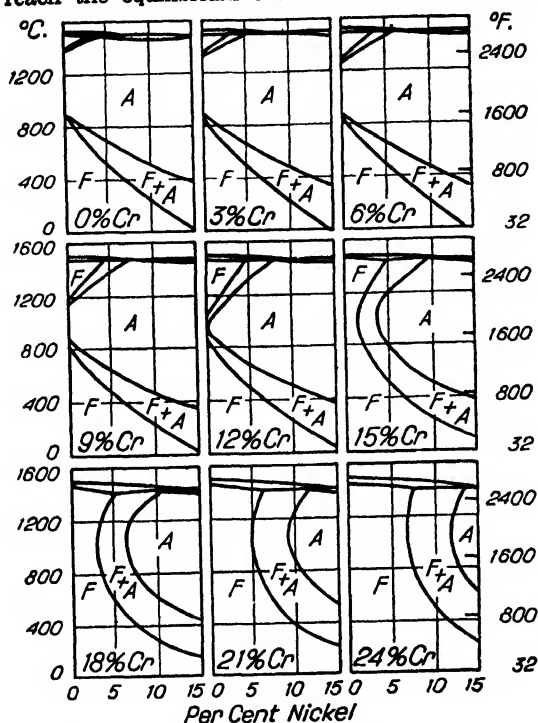

Fig. 10—The effect of nickel upon the constitution of various alloys of constant chromium content. (Constant chromium sections of the Solid Three Dimensional Ternary Diagram, temperature vertical).

Fig. 11—Probable Equilibrium Diagram of the 18 chromium-8 nickel alloys of various carbon contents.

preserve the constitution set up at some higher temperature during a previous heating. This means, in general, that the alloys are more austenitic at room temperature than corresponds to the true equilibrium at that temperature. As a result, special time consuming methods of working the alloys ("stirring" them, in effect) followed by prolonged heating is necessary to discover what the trend toward equilibrium really is. When this is done the indications are that at temperatures at or below about 570°F. the equilibrium state shown in Fig. 7 would result. In contrast, Fig. 8 shows the distribution of the alpha iron-chromium and the gamma iron-nickel phases and the mixed phase regions over their respective composition ranges when the alloys are rapidly cooled from the temperature level of Fig. 5.

A wide variety of iron alloys essentially carbon free but carrying either chromium or nickel, or both, to the extent of perhaps 8 or 10%, become martensitic as to structure after even a moderately rapid cooling from the austenitic

temperature. The hardness, although definitely greater in this condition than when composed of polyhedral ferrite grains, is not comparable with the martensite of carbon steel carrying even as little as a quarter of one per cent carbon. These carbonless martensitic structures serve to indicate that the acicular mode of transformation relates to the low transformation temperature rather than to composition.

Apart from the behavior of the brittle compound, the only significant difference between slow and rapid cooling within the ordinary range of rates is observed with low alloy content, when the alpha iron product is "massive" or polyhedral ferrite in the former instance and martensite in the latter; but beyond a few per cent of nickel or of chromium the transformation product is always a "carbonless" martensite.

Furthermore, the alloys which are shown as being wholly or largely ferritic in Fig. 7 (which represents equilibrium conditions at 570°F.), and as being normally austenitic in Fig. 8 (which represents maximum

austenite retained by rapid cooling to room temperature), are subject to inordinate hardening by cold work, that is, in the manner of Hadfield's manganese steel. This extraordinary pick up of strength and hardness is regarded as being due to the formation of ferrite from austenite at a room temperature at which the condition of the ferrite must be that of martensite. This view is strengthened by the observation that higher carbon content enhances this hardening effect of cold work. In any event, this hardening, accompanied by the acquisition of ferromagnetism denotes an allotropic change in an unstable alloy brought about by the stirring action of cold deformation.

Since the compositions carrying about 18% chromium and about 8% nickel are commercially familiar, the sections of the ternary diagram representing each of these two constant concentrations, with the other element variable, are shown in Fig. 9. A somewhat more extended assortment of constant chromium sections is shown in Fig. 10.

The practical usefulness of a discussion of the iron-chromium-nickel system is increased by some consideration of the effects of carbon since it is extremely difficult to produce the alloys free from carbon. The solubility of carbon in the austenite-nickel (gamma iron) solid solutions rapidly decreases as the chromium content increases. Graphite may form in the high nickel alloys with low chromium. The characteristic influence of carbon upon the commercial austenitic iron-chromium-nickel alloys is exemplified in Fig. 11 for the 18 chromium-8 nickel alloy. This shows the state of affairs to be found at equilibrium and is far different from what is ordinarily encountered, as shown in Fig. 12, owing to the extreme sluggishness and negligible reaction rate at the lower temperatures.

Nickel lowers the dissolution rate of its solid solution in iron in essentially all reagents, and hence retards corrosion. When this effect is superimposed upon the passivating effect of chromium when present in excess of some 10%, an unusual resistance to any attack under oxidizing conditions is conferred upon the alloy. When, then, nickel and chromium are so added as to produce an austenitic, work hardening alloy, remarkable properties are realized, as in the "18-8" composition now widely employed.

Under the special case of gaseous corrosion in which atmospheric oxygen attacks metal at elevated temperatures, the iron-nickel-chromium alloys are likewise remarkable. Fortunately, these higher chromium-nickel alloys also possess good strength at elevated temperatures, and this combination of slow oxidation and good high temperature strength makes these materials almost indispensable in the various chemical industries.

In this article little can be included of the industrial significance of the commercial, carbon-bearing, iron-nickel-chromium alloys, and the reader is therefore referred to the chapters on "Stainless Steels" in this handbook.

Physical and Mechanical Properties of Iron

By Reid L. Kenyon*

General—The purpose of this article is to give a condensed statement of the physical and mechanical properties of the metal, iron, as reported in scientific literature.

Acknowledgment—The data and information for this article have been selected from a number of sources, but mainly from the book, "The Metal—Iron" by H. E. Cleaves and J. G. Thompson, edited by Frank T. Sisco, and published by the Engineering Foundation, New York. This very complete volume contains an extensive bibliography of over one thousand references. The statements and data from the volume, "The Metal—Iron", have been freely used in the compilation of this article, and the cuts are reproduced by permission of the Engineering Foundation.

Fig. 1—Crystalline form of iron. (a) Body-centered cubic packing, alpha and delta iron; (b) alpha and delta iron, body-centered cubic; (c) face-centered cubic packing, gamma iron; and (d) gamma iron, face-centered cubic.

Also, data were selected from the U. S. Bureau of Mines Bulletin No. 296, by O. C. Ralston. Data from other sources have been selected and in such cases an endeavor has been made to give credit to the particular author.

The data are usually from tests on material prepared by special methods in the laboratory, so it must be appreciated that considerable variation in the property values must result in many cases. An attempt has been made, as far as the data were available, to include the results of tests on commercially available materials, such as carbonyl iron, electrolytic iron, and ingot iron.†

On account of the variability in composition and treatment of the many different samples of iron used by various investigators, the values given should be considered as the best approximations now available for the different properties and should not be used for specification purposes.

Composition—Table I gives the typical composition of several common forms of iron which are available commercially. The analyses of a number of individual

†In this article "Ingot iron" refers to "Armco ingot iron."

Atomic Structure

Isotopes—The Aston mass spectrograph has shown the existence of two isotopes, Fe (54) and Fe (56), which are present in the proportions of 1-20.

Atomic Number—The atomic number is 26.

Atomic Weight—The atomic weight is 55.84.

Nuclear Structure—The nucleus of the iron atom consists of 14 alpha particles and two negative charges. The nucleus therefore carries a 26-fold positive charge

which is compensated by the 26 electrons in the outer shells. The ratio of the number of outer electrons to the total positive charges is 0.536. This quantity is a measure of the nuclear stability which is quite large for iron.

Arrangement of Electrons—The 26 outer electrons are believed to be distributed on four shells as follows: The inner K-shell 2, L-shell 8, M-shell 14, and the outer N-shell 2.

Atomic Radius—As reported by Morse, the atomic radius for alpha iron is 1.236×10^{-8} cm. and for gamma iron is 1.284×10^{-8} cm.

Atomic Volume—By this term is usually meant the volume of a gram-molecular weight, and for iron at room temperature this is 7.1 cm.³ The volume of an individual atom can be derived from this by dividing by Avagadro's number which gives 11.7×10^{-24} cm.³ for alpha iron at 16°C.

Crystallographic Properties—Iron is found to have two crystallographic forms: Body-centered cubic for alpha, beta, and delta iron, and face-centered cubic for gamma iron (Fig. 1). The dimensions of the unit cube (lattice parameter) vary with temperature as shown in Fig. 2. The body-centered cubic lattice can be considered as two interpenetrating simple cubic lattices whose coordinates are (0 0 0)

Fig. 2—Effect of temperature on lattice parameter of iron. (Sato.) Fig. 3—Effect of cold work on the density of ingot iron. (O'Neil.) Fig. 4—Effect of annealing on the density of cold drawn ingot iron (Tamaru) Fig. 5—Effect of annealing on the density of cold hammered ingot iron. (Ishigaki.) Fig. 6—Effect of cooling rate on Ar₃ point of iron. (Goertens.)

Fig. 7—Specific heat of iron. (Austin.)

and $(\frac{1}{2} \frac{1}{2} \frac{1}{2})$. The face-centered lattice is really made up of four interpenetrating simple cubic lattices and there are, therefore, four atoms in the elementary cell whose coordinates are (0 0 0) $(\frac{1}{2} 0 \frac{1}{2})$ $(\frac{1}{2} \frac{1}{2} 0)$ and $(0 \frac{1}{2} \frac{1}{2})$.

Density—The density determinations on individual specimens may be conducted with great precision but the results apply only to the small pieces used in the test and results carried out to several significant figures are therefore of questionable value, at least as a measure of the density of the material as a whole. Three common methods for determining density of iron are: Direct measurement, calculation from the lattice constant as determined by X-ray examination, and extrapolation to zero content of alloying element of a series of iron alloys. Table II gives average values computed by Cleaves and Thompson from the work of a number of investigators.

Variation of Density with Temperature—The density at temperatures above room temperature are generally determined by calculation from either the coefficient of thermal expansion or the lattice constants. Lack of accurate data on

Column (2) calculated from lattice constants determined by Westgren and Phragmen. Column (3) calculated by Ralston from thermal expansion data of Honda and Sato.

volume changes at the transformation points results in the values for density above the A₂ point being unsatisfactory. Table III combines data from several sources on the density of iron at elevated temperature.

Variation of Density with Cold Working—Cold working lowers the density of iron as shown by the data obtained by O'Neill on ingot iron, Fig. 3. Tamaru and Ishigaki studied the effect of annealing at various temperatures on the density of cold worked ingot iron and their results are shown in Fig. 4 and 5. When heated above the A₂ point, the density is restored to the value it had before cold working.

Transformation Points—The transformation points are the temperatures at which the various polymorphic changes occur. Some of these points are well accepted, while others are in much question, being merely discontinuities in some physical property curve.

Owing to the wide variation in the methods used for determining these transformation points, considerable difference in the results is to be expected. Some of the methods that have been used are: Heating and cooling curves and variations of this method, including differential curves; calorimetric measurements; magnetic tests; thermoelectric phenomena; electrical resistance measurements, and dilatation.

A₁ Transformation Range—This is the Curie point of pure iron below which iron is magnetic and above which it is not. X-ray methods have shown paramagnetic α iron (formerly called β) to be of the same crystal structure as magnetic α iron. The magnetization is not all lost at one point, most of it being gone on heating up to 768°C., but remaining traces being detectable up to 791°C. This upper temperature depends on the sensitiveness of the instruments used.

Heating and cooling curve methods have yielded quite consistent results and for several investigators show that the greatest thermal effect of the A₁ transition

occurs at 768°C. Sauveur has found that previous heat treatment has some effect on the determination, successive heatings tending to gradually raise the value to a constant temperature.

Calorimetric methods have been used by many investigators, and Ralston has studied and interpreted their data and gives an average value of 781°C. corresponding to the discontinuity in heat content.

Values obtained by means of magnetic tests are influenced by strength of field and sensitiveness of instruments. As already stated, the magnetic effect falls off rapidly at about 768°C., but Honda claims it does not reach a constant value until about 790°C.

Thermocouples made of iron and platinum or iron and copper have been used for determination of the transformation points, but contamination of the couples has been one frequent source of error in these measurements.

Broniewski and Belloc found a discontinuity in the emf.-temperature curve at about 795°C. The work of Burgess and Scott showed a definite change in direction of the curve at 768°C. This was an electrolytic iron sample against platinum. All of their curves (for heating) had maxima at about 780°C. It has been suggested by Ralston that the latter is the real A₁ point as revealed by thermoelectric means, the 768°C. point being due to heat absorption known to reach a maximum at that temperature.

Some experimenters have reported discontinuities in the electrical resistance curve at a temperature corresponding to the A₁ point. For example, Honda and Ogura report such a point at 798°C. Burgess and Kellberg used a method estimated to give a precision 1,000 times greater than that of Honda and Ogura and found a perfectly smooth curve. This would indicate that electrical resistance data fail to show the existence of the A₁ point.

The only evidence available on the dilatometric changes corresponding to the A₁ point are those contributed by Benedicks whose dilatometric measurements have been accepted as precise, but whose temperature measurements and control have been criticized. His data show a slight indication at 760-775°C., but this is subject to interpretation.

Fig. 8—Effect of temperature on the thermal conductivity of iron.

Fig. 9.—Coefficient of linear thermal expansion of iron at low and high temperatures.

A₂ Transformation Range—This is the temperature at which pure iron undergoes a crystallographic change from a body-centered to a face-centered cubic lattice. The change is not instantaneous and consequently there is some difference between the transition temperature on heating and cooling and also with variation in heating and cooling rate. Values are given for A_c (heating) and A_r (cooling). Ralston believes the best values to be those of Burgess and Crowe, who tried several cooling and heating rates and extrapolated to zero rate. Their corrected figures for zero rate are A_c, 909 ± 1°C., and A_r, 898 ± 2°C. These values are determined from the heating and cooling curves. Oberhoffer quotes the later work of Ruer and F. Goerens, which established the $\gamma \rightleftharpoons \beta$ transformation at 906°C. ± 1° (Fig. 6).

The specific heat method is regarded as giving the value for A_c and the method of carrying out such tests gives results corresponding to zero heating rate. Oberhoffer and Grosse, and Umino both report 906°C., but the values are not considered precise.

Magnetic methods give the values in Table IV.

Table IV
Experimental Values for A₂ Transformation Points Determined by Magnetic Methods

Observer	Date	A _c , °C.	A _r , °C.
Honda and Takagi.....	1915	911	898
Honda and Takagi.....	1915	908	889
Ishiwara	1917-18	898	890
Terry	1917	918	903

Thermoelectric methods using platinum for reference have been used by Burgess and Scott. They found that the A_c transition begins at 906°C. on heating and continues to 912°, while the A_r transition begins at 900°C. on cooling and is complete at 896°C. Later work by Berliner confirmed these temperatures.

Electrical resistance methods are not so sensitive as some of the others, but Burgess and Kellberg, by using high precision methods, showed A_c beginning at about 900°C. and continuing to 911°C., while A_r began at about 887°C. and finished at 872°C.

Fig. 10—Effect of temperature on the vapor pressure of iron.

Honda and Miura working with ingot iron at heating or cooling rates of 2°C. per min. found A_c begins at 860°C. and ends at 905°C., while A_r begins at 889°C. and ends at 850°C. Recent work on hydrogen annealed carbonyl iron showed a spread of only 2 or 3°C. and even of only 1°C. between A_c and A_r temperatures. An A_c value of $907 \pm 2^\circ\text{C.}$ was obtained using a heating rate of 0.125°C. per min., while the A_r point for the same cooling rate was 907°C. Cleaves and Thompson observe that "the spread between A_c and A_r points can be practically eliminated by technique and methods which are now available, but further work is necessary to decide whether or not the temperature of the A_c transformation is appreciably higher for extremely pure iron than for somewhat less pure material."

A_c Transformation Range—Magnetic and thermal tests are the principal ones that have been used to determine this point. It was first discovered by Ball and later by Osmond and Curie. The samples of these investigators were impure, which is no doubt the reason for their low results (1300°C.). More recent determinations are given in Table V.

Table V
Experimental Values for A_c Transformation Point

Observers	Date	A_c , °C.
Thermal Methods:		
Gontermann	1908	1411
Ruer and Kaneke.....	1914	1420
Ruer and Klesper.....	1914	1401
Hanson and Freeman.....	1923	1400
Wever	1927	1401
Magnetic Method:		
Weiss and Foex.....	1911	1395
Ishiwara	1917	1390
Terry	1917	1406

Ralston gives the above values (except Wever) and concludes that the work of Ruer and Klesper and of Terry seems to be the most consistent and best described, and averages their data to get A_c at 1403.5°C.

Specific heat determinations of Wüst, Meuthen, and Dürrer showed A_c to be at 1404.5°C., while Oberhoffer and Grosse found it to be at 1401°C. As Ralston points out, these methods are not as precise as magnetic or thermal tests but give good confirmation of the above values determined by those methods.

Heat Capacity, Specific Heat, Entropy—Although considerable data have been published on these properties, there are numerous discrepancies between them which makes a concise presentation difficult. Both Ralston and Austin have made critical surveys of the results available. Cleaves and Thompson prefer Austin's review because it is more recent than Ralston's and includes data obtained by improved methods.

The variation in specific heat with temperature is shown in Fig. 7. In this discussion "specific heat" refers to the rate of change of heat content at a given temperature (sometimes called "true specific heat" in the literature), and "mean specific heat" refers to the average rate of change over a given temperature range.

Table VI, adapted from Cleaves and Thompson, gives values selected by Austin for entropy, heat content, free energy, and specific heat of both alpha and gamma iron over the entire range from absolute zero to the melting point. The specific heat of liquid iron has been reported by various investigators (Wüst, Meuthen, and Dürer; Umino; Oberhoffer and Grosse), at values varying from 0.142-0.222 cal. per g. The average of four reported data is 0.177 cal. per g.

Table VI

Heats of Transition—There is no discontinuity in the total heat curve at the A₂ point and Ralston interprets this as indicating only a change in specific heat and not a real heat of transition. Numerous values of heat of transformation are given in the literature for the A₂ point, but these may be the magnetic component of the specific heat integrated over a more or less wide range of temperature. Ralston states: "The true heat of transition of A₂ is therefore zero, unless we look on the heat accompanying the magnetic changes as a distributed (over a tempera-

Fig. 11—Electric resistance of iron at low and elevated temperatures.

Austin considered Ralston's value as the most probable one for the heat effect at the A point.

ture range) latent heat. This latter idea is quite permissible, although not in common acceptance."

The values for heat of transition at the A point have for the most part been determined by measuring the heat content above and below the transition temperature; and since the results are small differences between large numbers, the variations recorded in the literature are not surprising. Since Ralston calculated his value of 4.9 cal. per g. from an average heat content curve, Klinkhardt and Esser and Bunghardt have made direct determinations of the heat absorbed during the transformation. The average of their results gives 3.63 cal. per g. or 203 cal. per g.-atom.

Yap computed, from Umino's heat content data, the heat effect during the alpha-gamma change when this occurred at various temperatures.

Although Ralston's value of 1.7 cal. per g. or 94.9 cal. per g.-atom for the heat effect at the A point is somewhat lower than Umino's subsequently reported determination of 1.86 cal. per g., Cleaves and Thompson state that

900	5.6	1400	-1.9

Fig. 12—Effect of annealing on the electric resistance of cold worked iron.

Thermal Conductivity—Most of the published determinations of this property are for impure specimens. This no doubt accounts for much of the disagreement between the results of different workers, although Grüneisen and Goens found that impurities had a much greater effect at low temperatures than at room temperature. The data from several sources are shown in Fig. 8.

Thermal Coefficient of Expansion—The coefficient linear thermal expansion is the increase in length per unit length for 1° rise in temperature, and is sometimes referred to as the "true coefficient of expansion." The average expansion over a range of temperature is the mean coefficient of expansion over that range.

Fig. 9 shows the results reported by various investigators, while Table VIII gives values selected by Cleaves and Thompson. Mean coefficients for various temperature ranges are given in Table IX.

Austin and Pierce found that the expansion above 600°C. was sensitive to small changes in composition and treatment, and they did not give selected values above that temperature. The ones marked () were averages by Cleaves and Thompson, not for precise values but to indicate the trend of the relation for higher temperatures.

The thermal coefficient of expansion for gamma iron is given in Table IX; that for delta iron has been reported by Sato to be 16 millionths per °C. Ralston recalculated Sato's data and got 12.5 millionths per °C., while calculations based on Schmidt's X-ray data gave 19.5 millionths per °C.

The expansivity of molten iron has been calculated from density determinations but shows wide variations according to the data used. Berlin's data yield 0.00043 as the coefficient of cubical expansion per °C. between the melting point and 1700°C., while the results of C. Benedicks, N. Ericsson, and G. Ericson give 0.00014 per °C. between the melting point and 1600°C.

The thermal expansion at the transformation points has been investigated in the course of determinations of these points but may be summarized here. There is no agreement regarding the occurrence of a definite amount of expansion at the A_s point; certain maxima and minima have been reported at various temperatures, but even these are not consistent. There is a sudden contraction as iron is heated through the A_s range. Although this change is generally considered to be reversed

on cooling, Austin and Pierce and others have found that the expansion on cooling was less than the contraction on heating in the case of the purest specimens tested. Cleaves and Thompson give the results of several investigators and the values vary from 0.82-3.8 thousandths (linear change at the A_1 point, $\Delta L/L$). The metal expands suddenly at the A_1 point, the only direct determination being by Sato as 0.851 thousandths $\Delta L/L$. Calculations based on X-ray data give from 1.4-3.2 thousandths $\Delta L/L$.

Fig. 13—Hysteresis loop for ingot iron and hydrogenized iron.

facing the difficulty of reconciling this with the later determination† of Jenkins and Gaylor (1527 \pm 3°C.), suggested that the value of 1535°C. (2795°F.) be accepted as a rounded value for the best present approximation of the melting point of iron.

‡Extrapolated below the melting point. All values in this column are extrapolated beyond the experimental range.

**This vapor pressure corresponds to the boiling point under "standard conditions."

*They report the following analyses of three electrolytic irons used in their tests: Langbein-Pfianhauser electrolytic iron, 0.012 C, 0.00 Mn, 0.007 P, 0.00 S, 0.00 Si, 0.008 Cu; C. F. Burgess electrolytic iron, 0.012 C, 0.00 Mn, 0.004 P, 0.00 S, 0.013 Si; J. R. Cain electrolytic iron, 0.004 C, 0.00 Mn, 0.0006 P, 0.004 S, 0.001 Si, 0.008 Cu.

†Jenkins and Gaylor used an electrolytic iron whose composition before melting was 0.005-0.007 C, trace Mn, 0.002 P, 0.0-0.001 S, trace to 0.009 Si, trace to 0.006 Cu, and after melting was 0.01 C, trace Mn, 0.014 P, trace S, 0.03 Si.

Boiling Point and Vapor Pressure—Table X gives the results of several investigators and these are plotted in Fig. 10. The boiling point is the temperature at which the vapor pressure equals 760 mm. of mercury. Cleaves and Thompson suggest that a rounded value of 3000°C. should be used for the boiling point because

the most reliable values available were determined indirectly and under experimental conditions likely to lead to inaccuracies.

Electrical Properties—The electrical resistance of iron is greatly influenced by impurities and by the previous thermal and mechanical treatment so that reported values are often discordant. Cleaves and Thompson give a complete discussion of this subject and the following data are largely abstracted from their presentation.

The average of nine different workers' results for the resistance at 0°C. gave 9.43 microhm-cm. for electrolytic iron, of seven results for reduced iron, 9.29 microhm-cm., and of three for commercially pure open hearth iron, 9.50 microhm-cm., while a single value given for Swedish iron was 13.2 microhm-cm., all at 0°C. Cleaves and Thompson consider a rounded value of 9.8 microhm-cm.

at 20°C. to be the best present approximation for the resistivity of iron. This would be equivalent to 9.67 microhm-cm. at 0°C. using 0.0065 per °C. as the fundamental coefficient.

Fig. 11 gives the electrical resistance of iron from the lowest to the highest temperatures that have been investigated. There are no data available for high purity iron between 1100°C. and the melting point. The values shown for molten iron were obtained by Boremann and Wagenmann by extrapolation to zero carbon content for a series of carbon steels. Table XI combines data from several sources as reported by Cleaves and Thompson. They state that Meissner's values of resistivity are probably the best for sub-zero temperatures, while those of Burgess and Kellberg are considered most probable above zero.

Temperature Coefficient of Electrical Resistance—(Effect of

Fig. 14—Magnetization curves for ingot iron and high purity iron. (Yensen.)

Fig. 15—The effect of hydrogen treatment on the permeability of annealed iron. (Cloff, according to Ellis and Schumacher.)

Temperature on Electrical Resistance). The resistance of iron, like other metals, changes with temperature and the coefficient expressing this relationship, as defined by the following equation, is tabulated for several irons in Table XII.

$$R_t - R_{t'}$$

$$\alpha = \frac{R_t - R_{t'}}{R_{t'}(t - t')}$$

Effect of Mechanical and Thermal Treatment—Cold working increases the resistivity, but reannealing of cold worked iron lowers the resistivity to its initial value. Bardenheuer and Schmidt found practically no change in resistivity of electrolytic iron cold drawn various amounts up to 95% reduction in area, but

Tammann and Moritz obtained a maximum increase in resistivity of about 5.7% by cold working 99.8%. Annealing at 600°C. (1110°F.) restored the iron to its original resistivity. Fig. 12 is taken from the work of Tammann and Moritz.

Fig. 16—Variation of the permeability of annealed electrolytic iron with temperature. (Terry.)

Effect of Hydrostatic Pressure—Beckman found the pressure coefficient of electrical resistivity of Swedish iron of low purity (fundamental coefficient of 0.0048) to be 27.4×10^{-7} per atmosphere between 425 and 2097 atmospheres at 0°C. ($\alpha = 1/R \times dR/dP$). Bridgman measured the pressure coefficient on basic open hearth iron (fundamental coefficient = 0.0062) and obtained 24.9×10^{-7} per atmosphere at 0°C. and zero pressure and 21.9×10^{-7} per atmosphere at 0°C. and 12400 atmospheres.

Thermoelectrical Properties—

Table XIII gives the thermal electromotive force produced by bimetallic couples of iron and other metals. The values are in millivolts and are considered positive if the current flows from the iron to the other metal at the junction which is at 0°C. The data were obtained in some cases on samples of unknown

Table XIII

‡Neutral point 247°C.

purity and would not be exactly duplicated on other specimens but are given as an indication of the magnitude of the thermoelectromotive forces produced.

Electrochemical Equivalent—This constant is computed from the atomic weight and the valence and there are therefore two values for iron: 0.1929×10^{-3} g. sec.⁻¹ ampere⁻¹ for trivalent iron and 0.2893×10^{-3} g. sec.⁻¹ ampere⁻¹ for bivalent iron.

Magnetic Properties—The magnetic properties, like the electrical are quite sensitive to small changes in treatment and amount of impurities. Samples of high purity iron prepared by long time hydrogen annealing just under the melting point have furnished new and interesting values for the magnetic properties of iron, but the concomitant effect of large grain size no doubt is also present and the results are included here with the caution that grain size may become of increasing influence on the magnetic properties as the purity increases.

Fig. 13 shows hysteresis loops of ingot iron and hydrogenized iron as determined by Cioffi, while magnetization curves for these materials are illustrated in Fig. 14. The permeability of the hydrogenized iron (0.005 C, 0.028 Mn, 0.004 P,

Fig. 17—Variation of the hysteresis constants of annealed electrolytic iron with temperature. (Terry.)

0.003 S, 0.0012 Si, 0.003 O, 0.0001 N₂) is enormously greater at low inductions than irons of commercial purity, but the difference fades out at higher inductions. This is shown in Fig. 15.

Effect of Temperature—In studying the effect of temperature on permeability of Burgess' electrolytic iron, Terry found that this depended on the field strength as shown in Fig. 16. His results on the effect of temperature on the hysteresis constants are given in Fig. 17.

Effect of Grain Size—The work of Sizoo on electrolytic iron (0.024 C, 0.012 S, 0.014 Si) is shown in Fig. 18, while that of Yensen and Ziegler is given in the following equations:

Coercive force = H_c (oersteds).

Hysteresis loss = W , ergs/cm.³/cycle.

Minimum reluctivity = ρ_{min} (thousandths).

For carbon less than 0.002%.....	$\rho_{min} = 0.34 \times 10^{-8} N$ $H_c = 0.0018 N$ $W = 56 N$
For carbon 0.002-0.004%.....	$\rho_{min} = 0.21 \times 10^{-8} N$ $H_c = 0.00114 N$ $W = 34.4 N$
For carbon 0.004-0.008%.....	$\rho_{min} = 0.46 \times 10^{-8} N$ $H_c = 0.0025 N$ $W = 75 N$

Where N is the number of grains per sq.mm.

The effect of orientation, no doubt, is present in the case of the larger grain sized specimens, but does not seem to have been considered by the investigators quoted.

Fig. 18—Effect of grain size of electrolytic iron on hysteresis loss and maximum permeability. (Sizoo.)

Effect of Cold Work—Cold working has a deleterious effect on the magnetic properties of iron. The effect of various amounts of cold reduction on the hysteresis loop of electrolytic iron (polycrystalline) as determined by Gries and Esser is shown in Fig. 19. Cleaves and Thompson state that cold working decreases permeability and increases residual induction, coercive force, and hysteresis loss and leaves only the saturation intensity unaffected.

Optical Properties—Emissivity determinations on high purity iron are rare and even when specimens of such material have been used the experimental procedure has often affected the purity, as when the source of heat was an arc between carbon electrodes. The best accepted values are those of Burgess and Waltenberg in Table XIV, determined with a micro pyrometer:

Table XIV
Emissivity of Iron at Various Temperatures

State	Temp., °C.	Emissivity, %
Solid	1050	37.9
	1350	37.2
	1450	38.3
	1530	38.0
Liquid	1535	38.5
		Average 38.8

The above values are all for $\lambda = 0.65 \mu$ and the average should probably be rounded to 37%.

Emissivity values for iron and steel as measured in various industrial operations may differ from this due to oxide on heated surfaces of solid metal and

Fig. 19—Effect of cold work on the hysteresis loop of polycrystalline electrolytic iron. (Gries and Esser.)

seem to have been the subject of investigation. Fig. 20 presents the combined results of several workers.

X-ray absorption data have been summarized by Compton from values published by Allen, Hewlett, Ahmad, Ishino, Richtmyer and Warburton, Bragg and Pierce, Martin, and Barkla. Compton's selected values are given in Table XV.

Table XV
X-Ray Absorption for Iron

Wave Length Microns	Compton's Selected Values	Wave Length Microns	Compton's Selected Values
0.017.....	0.058	0.500.....	14.3
0.057.....	0.08	0.600.....	23.3

Gamma Ray Absorption—The minimum apparent coefficient of absorption of gamma rays is as follows:

	100 (μ'/ρ)
Th — C''.....	3.28
Ra — C.....	3.99
Ms — Th ₁	4.15
U — X ₃	4.72

Index of Refraction—The index of refraction depends on the wave length of the incident light. Of the results obtained by numerous investigators, those of Ingersoll seem the most reliable and are as follows:

λ in m μ	228	400	500	700	1000	2000	2250
n	1.30	1.68	2.09	2.73	3.19	4.02	4.14

floating slag on liquid metal. Cleaves and Thompson state that values between 40 and 45% for liquid metal or solid metal with a bright surface and as high as 90% for solid metal with an oxidized surface have been reported. The International Critical Tables, v. V, p. 244, gives the total emissivity for oxidized surfaces of steel as 79% at 200°C., 78.8% at 400°C., and 78.7% at 600°C.

The *reflectivity* determinations found in the literature are for the most part on iron of unknown composition. Moreover, the effect of impurities on this property does not

Mechanical Properties—Elastic Constants—Abram found ingot iron and mild steel have a slightly higher Young's modulus than medium and high carbon steel. They reported 30.1×10^6 psi. for ingot iron and considered that for pure iron in the annealed condition the value would be about 30.2×10^6 psi. Goens and Schmid determined Young's modulus for different directions in a single crystal of ingot iron and found it was more than twice as great in the [111] direction as in the [100] direction.

$E [100] = 19,000,000 \text{ psi. (13,500 Kg./sq. mm.)}$
 $E [111] = 41,000,000 \text{ psi. (29,000 Kg./sq. mm.)}$

Kimura and Ohno report the values in Table XVI for the elastic constants for single crystals of iron.

Table XVI
Elastic Constants for Iron (Single Crystals)

	[100]	[110]	[111]
Young's modulus, psi.....	18.9×10^6	31.3×10^6	40×10^6
Modulus of torsion, psi.....	16.1×10^6	9.6×10^6	8.5×10^6
Bulk or Voigt's modulus, psi.....	$S_{11} = 10.9 \times 10^6$	$S_{12} = -4.7 \times 10^6$	$S_{44} = 14.7 \times 10^6$
Elastic constants, psi.....	$C_{11} = 39.4 \times 10^6$	$C_{12} = 24 \times 10^6$	$C_{44} = 18.2 \times 10^6$

Other values reported for polycrystalline irons are 29,300,000 psi. for ingot iron as determined by Kenyon; 29,600,000 and 30,600,000 psi. for electrolytic iron as reported in the International Critical Tables and Grüneisen, respectively; and 29,400,000 psi. for carbonyl iron as given by Duftschmid, Schlecht and Schubardt.

Values for the modulus in torsion or shear modulus on polycrystalline irons are as follows:

Shear Modulus in Psi.

Ingot iron.....	11.77×10^6
Ingot iron.....	11.78×10^6
Electrolytic	11.45×10^6
Electrolytic	11.81×10^6
Electrolytic	11.66×10^6

Poisson's Ratio is generally considered to lie between one-fourth and one-third for most metals and is given for iron as 0.28 in various handbooks.

Compressibility—The compressibility of iron has been studied by various investigators, but the outstanding work in this field is that of Bridgman, who determined the compressibility of ingot iron. Cleaves and Thompson have summarized his findings and state that at 30°C. the mean compressibility between 0 and 10,000 kg. per sq.cm. was 0.566×10^{-6} kg. per sq.cm. and at 75°C. it was 0.572×10^{-6} kg. per sq.cm. over the same range of pressure. The pressure coefficient for this range of

pressure was 7.0×10^{-6} per kg. per sq.cm. and the temperature coefficient was 2.3×10^{-4} per °C. over the range of 30-75°C.

Adams found the compressibility of a specimen of Yensen high purity iron agreed with that of Bessemer steel within 1 part in 500 over a range of 0-7000 kg. per sq.cm. pressure.

Compression, Tensile, Fatigue, Impact, and Hardness—These values for polycrystalline irons at room temperature are given in Table XVII. The data presented are of necessity only a summary of selected values.

Fig. 20—Reflectivity of Iron.

Effect of Temperature on Mechanical Properties—Although variations in testing technique affect the results at room temperature, they have an even greater effect at high and low temperature. Speed of testing, shape of test piece, method of gripping, uniformity of temperature, and accuracy of temperature measurement are important factors, which, unfortunately, are frequently not mentioned in many reports of tests found in the literature.

Results obtained at elevated temperature may be divided into two groups: "Short time" and "creep." Tapsell and Clenshaw give the results shown in Table XVIII for ingot iron when using a Martens extensometer for determining the modulus at elevated temperatures. The loading was applied in steps. Total time to proportional limit about 20 min. Normalized bars 2 in. gage length and $\frac{1}{2}$ in. dia.

The work of Lea covered the temperature range of -40 – 1000°C . and in general his tensile values are lower than those of Tapsell and Clenshaw, and above the "blue brittle" range the elongation is greater. These results are shown in Fig. 21.

The maximum in tensile strength in the proximity of 200°C. is generally ascribed to the so-called "blue brittle" phenomenon. The temperature at which this maximum tensile strength occurs depends on testing speed; slower speeds throw it to lower temperatures, and if the test is made sufficiently slow (two months) at room

temperature, a strength is obtained approximately equal to that obtained at ordinary rates of testing in the "blue brittle" range.

The "creep" strength is considerably lower than the tensile strength determined in the short time test. The value obtained depends on the rate of creep chosen. Tapsell and Clenshaw have determined the strength of ingot iron at various rates of creep as shown in Fig. 22. The rate of creep used for curve 1 is less than 1×10^{-4} in. per day.

Mechanical Properties of Single Crystals
—Osmond and Frémont determined the yield strength in compression to be 19,800 psi. on cube faces and 24,200 psi. on

Fig. 22—Creep strength of ingot iron. (Tapsell and Clenshaw.)

octahedral faces of single crystals prepared from a decarburized steel rail (0.06 C, 0.30 Mn, 0.116 P, 0.02 S, 0.051 Si). This same material had a tensile strength of 39,500 psi. and a yield strength of 23,500 psi. perpendicular to a cube face and a reduction of area of 85%.

Edwards and Pfeil prepared single crystals from mild steel and found tensile strength values from 21,000-34,500 psi. on ten different crystals (orientations not determined); yield strength 4,300-5,600 psi.; elongation in 2 in. 30-54%; and Young's modulus $22.4-29.8 \times 10^6$ psi.

Osmond and Frémont's Brinell hardness results on above-mentioned specimen after annealing at 550°C. were 75 on cube face, 79 on dodecahedral face, and 81 on octahedral face. After annealing at 800°C. the corresponding values were 66, 69, and 76. Pfeil found on his single crystals a Brinell hardness of 80, which was the same in different directions of the crystal within the limit of accuracy of the test.

Effect of Grain Size on Mechanical Properties—Table XVIII-A gives the variation in tensile properties with grain size as determined by Edwards and Pfeil. Pomp found the Brinell hardness only slightly affected by grain size and reported the following: Brinell hardness 83 for 68 grains per sq.mm.; 87 for 827; 89 for 1350; 96 for 2310; and 95 for 3970 grains per sq.mm.

Hardness at Elevated Temperatures—Both dynamic and static hardness tests have been made on ingot iron by Tapsell and Clenshaw as shown in Fig. 23. O'Neill determined the scratch hardness at various temperatures of a carbon-free iron made by decarburizing a mild steel in hydrogen. These results are shown in Fig. 24. The hardness values are taken as the resistance to the production of a scratch 0.1 mm. wide at various temperatures.

Fig. 24—Change in scratch hardness with temperature. P13R—A cold rolled polycrystalline carbon-free iron, Mn 0.44%; Si 0.02%; S 0.028%; and P 0.020%. P13C same as P13R, but annealed. Grain 8 and Grain 7, two single-crystal grains, the scratch on No. 8 being in the [110] direction on a (100) face.

Hardness at Low Temperatures—The hardness of Swedish iron has been reported by Dewar and Hadfield and DeHaas and Hadfield as 101 at 15°C., 230 at -182°C., and 232 at -253°C., while Guillet and Cournot found the hardness of electrolytic iron to be 80 at +20°C., 77 at -20°C., 77 at -80°C., 95 at -110°C., and 269 at -182°C.

Alternating Stress Tests at Elevated Temperatures—Alternating stress tests on Haigh alternating stress machine at 2,400 cycles per minute with equal plus and minus stress on a basis of 10^7 reversals gave the following results:

°C.	Estimated Limiting Range of Fatigue Stress, psi.
18	28,700
100	24,000
200	25,500
300	33,400
400	28,900
500	12,300

Solubility of Hydrogen in Molten Iron

°C.	Volume of Hydrogen in cc. per g. of Iron (Standard Conditions)
1530 (M.P.)	0.272
1550	0.279
1650	0.310

Permeability of Iron to Hydrogen at Various Temperatures

°C.	Permeability
200	0.83
300	5
400	25
500	100
600	336

Permeability is the value of K in the equation $\frac{dm}{dt} = -K_{p_0} \frac{\Delta p}{\Delta z} dx dy$ where dm

is the mass of gas passing in direction z in time dt through a diaphragm of the solid of area dx dy and thickness Δz , the difference in pressure on the two sides of the diaphragm being Δp ; the minus sign indicates the flow is in the direction of decreasing pressure. p_0 is the density of the gas at zero C. and pressure of 1 atmosphere; dm/p_0 is the volume of dm at zero and 1 atmosphere.

p is expressed in atmospheres.

K is expressed in 10^{-6} cm³ per atm-sec.

Plastic Deformation of Iron

By C. H. Mathewson*

Block Movements of Slip and Twinning in the Crystal Lattice of Iron—Iron in common with other metals accommodates itself to plastic deformation by the gliding of crystal blocks or lamellae on one another, and this process ordinarily becomes one of pure translation in which the orientation of the crystal changes only as the gliding along planes cutting across the axis of stress application sets up a bending moment around an axis in the slip plane at right angles to the direction of slip. It is this bending or twisting of crystals and parts of crystals that gives rise to the preferred orientations or textures found in wrought metal. Such effects are important, as the physical properties of the metal are determined in large part by the orientation of its particles. The state of purity has a remarkable effect on the force necessary to start translation, or keep it in action, and in general on the dynamics of the process. As a principle of guidance it may be said that translation starts when the shear stress on a competent slip plane in a possible slip direction rises to a critical value, but, as the simple slipping process brings about change of orientation, the resolved shear stresses change and slip on one family of planes may soon be accompanied or replaced by slip on another family. In single crystals the normal outcome of the process may be fairly well predicted but in ordinary polycrystalline metal the mutual interferences among the grains lead to complications and there is no clearly accepted method of rationalizing the textures formed in such material by the translation process.

X-ray studies have revealed the general characteristics of textures¹ formed during the different industrial processes of working iron (and other metals), as indicated in a later paragraph, but it must be realized that data of this character give merely a rough indication of the preferred orientations of the crystals; as considerable deviation from any stated orientation always occurs, and the texture changes from one point to another in the object, for example, from surface to center in a drawn wire. It is this variability that renders the study of textures important as a method of controlling the conditions of plastic deformation in developing desirable directional properties in wrought metal for any particular purpose.

The gliding process may also become one of mechanical twinning, which requires that each slip plane shall move the exact fraction of the distance between atoms on the adjacent slip (twinning) plane that will set up anew the crystal lattice pattern in a changed or twin orientation. In iron, this process does not appear to be of great importance, as twin lamellae, or so-called Neumann bands are produced only under certain limiting conditions and do not usually represent the major effect of the plastic deformation. A general understanding of the elements and the simple mechanism of block movements defining the processes of translation or twinning may be obtained from the following outline.

Significant Directions and Planes—At temperatures above 2550 and below 1650°F. crystals of pure iron have their atoms arranged according to the simple body centered cubic pattern as illustrated in Fig. 1 of the article in this Handbook entitled "Physical and Mechanical Properties of Pure Iron".

For the purpose of considering displacements of atoms and planes by plastic deformation of the iron crystal, it is best to orient the body centered cubic unit of structure (Fig. 1) so that one of the body diagonals, *ab*, passing through two corner atoms and the central atom is in a vertical position. This and the other three body diagonals are lines or directions through the crystal along which the atoms make the closest possible approach to one another. When the crystal is forced to change its shape by the action of an external stress the atoms resist separation in these close packed strings and shearing occurs by some form of block movement in one or another of these four significant directions [111]. If we imagine other unit cells grouped around the first in Fig. 1, it is clear that the atom at each corner of the original cell belongs to a close packed string including the central atom of a respective neighboring cell. Similarly, the outlying corner atoms of these new cells belong to close packed groups derived from more

*Prof. of Metallurgy, Yale University, New Haven, Conn.

¹All references are given at the end of this article.

distant cells. Using the central string of atoms as an axis, a vertical plane may be rotated into various positions such as, a $c' b d'$, which is designated as a plane of form $\{110\}$, and the other shaded position designated $\{112\}$. Each plane furnishes some characteristic spacing of these close packed strings of atoms and some characteristic geometrical relationship between the atoms in this plane and those in a parallel plane passed through adjacent strings of atoms. These details can be studied in some form of a projection such as the one given in Fig. 2 in which all atoms are projected vertically into a plane of the form $\{111\}$ at right angles to the close packed string, ab (body diagonal), shown in Fig. 1.

It is evident in Fig. 1 that the atoms of the three different strings originating at a, c and d do not match one another in horizontal planes, while those originating at c, c' and c'' or at d, d' and d'' meet this condition perfectly.

Fig. 1

Fig. 2

Fig. 1—Body Centered Arrangement of Atoms with a Cube Diagonal in Vertical Position. 1, 2, 3, Body Centered Atoms From Adjacent Cells Occur at Each of These Levels.

Fig. 2—Projection of Atoms of Body Centered Cubic Lattice in a Plane Perpendicular to Close Packed Strings of Atoms (an Octahedral Plane). Atoms in the Plane of the Projection and 4th and 7th Planes Above Shown by Large Circles; in the 2d, 5th and 8th Planes by Smallest Circles; and in the 3d, 6th and 9th by Circles of Intermediate Size.

These differences in level are indicated in the projection of Fig. 2 by using circles of different sizes, with letters indicating the proper relationship to Fig. 1. A projection of this sort is of course competent to represent an indefinitely large number of unit cells piled on and around one another according to the plan of orientation selected. Planes of particular significance or interest may be selected for boundaries and in this projection (Fig. 2) dodecahedral planes $\{110\}$ of Fig. 1 are chosen for right and left-hand boundaries and trapezohedral planes $\{112\}$ of Fig. 1 for the upper and lower boundaries.

Within the figure it would be possible to draw many sets of parallel lines, bringing the projected strings of atoms into planes of various kinds. Thus a set of lines parallel to the vertical boundaries would represent the closest possible grouping of the strings into (dodecahedral) planes and inspection of the figure shows that there are two other sets of planes inclined 60° to the first set having these same characteristics.

Slip Planes and Directions—The common condition that plastic deformation of a crystal occurs in the direction of a line of closest atom packing by block movement along planes of the densest atom packing on which the stress intensity has reached the highest value would, in the case of a polished iron crystal oriented to correspond with Fig. 2 and loaded with maximum stress intensity in the direction of the atom strings (that is, perpendicular to the plane of the projection), cause one or more sets of slip bands to appear parallel to the most severely stressed dodecahedral planes. Actually, the slip bands observed in iron are of a more complex character, often irregular, forked or wavy and apparently unrelated to any principal plane of the crystal. O'Neill¹ and Pfeil² have observed bands parallel to planes of the form $\{112\}$ (horizontal boundaries in Fig. 2). Taylor and Elam³ emphasize the importance of the close packed atom strings in guiding the *direction* of slip, but consider the block movement to occur not along planes of simple indices but in

rod like bundles of atom strings whose boundaries are determined by stress considerations alone. Gough,⁶ in an elaborate analysis of the deformation of a single crystal of iron stressed in torsion, concludes that slip may occur in the direction of the close packed atom strings on quite a variety of planes containing these gliding elements, that is, planes of the form $\{110\}$, $\{112\}$, or $\{123\}$. These are the planes some of whose projections are shown by the lines drawn in Fig. 2. If the shear stress resolved in the direction of the close packed atom string is greater on one of the designated crystallographic planes than on any other conceivable plane, slip is likely to occur on the planes of this set without further complication. However, if the maximum shear stress occurs on some intermediate plane corresponding to the dotted line of Fig. 2, slip will occur on particular planes of the above designated forms located on both sides of the plane of maximum resolved shear stress $\{110\}$ and $\{123\}$, in Fig. 2. Under these conditions the slip bands will be of a duplex type with an average slope corresponding to the dotted line of Fig. 2. Fahrenhoust and Schmid⁶, however, considered $\{123\}$ the most probable planes of slip and Sauerwald and Sossinka⁷ found only the traces of these as slip planes after compression at room temperature.

Most recently, Barrett, Ansel and Mehl¹⁰ have verified Gough's general conclusions, but find that in silicon ferrite, either a low temperature or a high silicon content causes slip to be confined wholly to planes of the form $\{110\}$.

Severe Deformation—As the slipping proceeds in any crystal the process tends to become more complicated owing to a rotation which accompanies the block movement and consequent increase of stress in other eligible slipping directions. Large amounts of deformation therefore bring many different slip planes into play and in the case of ordinary polycrystalline material the process is further complicated by inhomogeneity of the force field at the grain boundaries. Hardening accompanies deformation of this character perhaps owing to an increased resistance to slip through the minute blocks of crystalline material which in moving past one another have developed slight differences of orientation (nonuniform curvature or lineal nonregistry at the boundaries).

Preferred Orientation Under Various Forms of Stress—In spite of the complex mechanism of the slipping process the crystalline particles of metal worked into a given form by continued application of stress in some prescribed manner finally become forced into positions closely approximating a definite and characteristic *preferred orientation*⁸. Simple stretching brings a cube face diagonal $[110]$ into the axis of the rod with a radial disposition of a corresponding set of cube edges $[001]$ in the different crystals. In cold drawn wires $[110]$ also occurs as the fiber axis. Under compression⁴ a body diagonal $[111]$ and to a lesser extent a cube edge occurs in the direction of compression with a cube face diagonal in the radial position. In torsion the cube face diagonal and to some extent the $[112]$ direction becomes the fiber axis with the body diagonal tangential. Cold rolling brings a face diagonal into the direction of rolling and a cube face into the plane of rolling.

Twinning—Planes of trapezohedral form $\{112\}$, parallel to the sides of the triangle outlined in Fig. 2, have the atoms of their close packed strings at the same level in a given horizontal section. In passing from one to another of these adjacent parallel planes, the strings shift laterally into positions half way between their former positions and vertically so as to bring the atoms either one-third or two-thirds of a full atomic distance above the atoms in the first plane, depending upon the direction of progression. If, beginning with a certain plane, say the one whose projection forms the base of the triangle in Fig. 2, the atoms in the next plane towards the bottom of the figure are brought one-third, instead of the normal two-thirds, of an atom distance above the atoms in the first plane, and the atoms in the third plane two-thirds, instead of the normal one-third, above, the altered region is said to be twinned with respect to the rest of the crystal. This change has been effected in the lower rectangular area which, therefore, constitutes the projection of a twin band.

Twinning by Pure Shear—The mechanical action of pure shear, in which the distance traversed by any particle in the direction of shear is proportional to its distance from the plane of shear, would produce this result, assuming the first plane (base of the triangle) to be the plane of shear and the shearing movement on the next plane to be exactly one-third of the distance between atoms in the close

packed string. This is believed to be the mechanism of mechanical twinning in iron.^{9, 10}

Close observation of Fig. 2 will make it clear that this same structural change may be obtained by shearing along any one of the three families of planes of the form $\{112\}$ represented by the sides of the triangle and that no other twin configuration is possible in this projection. However, since there are three additional body diagonals representing close packed strings of atoms in the iron lattice, three other projections each of them competent to illustrate the formation of a new twin configuration by shear along any one of three additional planes of the form $\{112\}$ are possible.

Infrequency of Twinning in Iron—So many planes are available for deformation by the ordinary process of slip that the much more restricted or specialized form of slip necessary for twinning would be expected to occur only exceptionally in pure iron. Stiffening of the lattice by alloying favors the occurrence of twinning. Somewhat brittle coarse grained ferrite containing silicon or phosphorus twins readily when deformed by impact. Coarse grained Armco iron also twins readily by impact at room temperature. It is reported¹¹ that pure ferrite twins readily even by slow deformation at the temperature of liquid air. Barrett, Ansel and Mehl in their recent investigation¹² of the plastic deformation of iron have demonstrated that twinning, which could be produced in pure iron by slow deformation (torsion) at $-200^{\circ}\text{C}.$, occurs at higher temperatures with increasing silicon content; until, with approximately 5%, it is the favored mechanism of deformation close to room temperature. It is followed in this relatively brittle alloy by cleavage, and then slip on planes of form $\{110\}$ as the temperature is further increased. Even under the most favorable conditions only thin sections of a crystal can be stressed in the exact manner necessary to produce the twin structure. Twinning in iron is therefore observed only in the form of thin lamellae usually called *Neumann bands*.

Deformation of Face Centered Cubic Iron—Ordinary grades of iron and likewise metal of exceptional purity containing only minute traces of the most tenaciously adherent impurities such as oxide, nitride, or carbide, when heated above $1650^{\circ}\text{F}.$, but not above 2550° , have their atoms arranged according to the face centered cubic pattern illustrated in Fig. 1d of the article on Physical and Mechanical Properties of Pure Iron given in this Handbook. (According to a recent accurate determination¹³ the lower A_3 point lies between 1650 and $1675^{\circ}\text{F}.$ in very pure iron). While no detailed study of the slip planes and directions brought into play by hot working pure iron in this range of temperature appears to have been made thus far, there is little doubt that the mechanics of deformation are analogous to those observed in aluminum¹³, copper¹⁴, and other face centered cubic metals.

In wrought and annealed austenitic steels in which iron has been alloyed so as to preserve the face centered cubic arrangement of atoms, the microstructure is strikingly similar to that of the common face centered cubic alloy, alpha brass, even exhibiting the familiar twin bands which are seen in both metals after recrystallization following plastic deformation. This points to a similarity of the deformational process in both cases and the analogy in all probability may be extended to include the behavior of pure iron at elevated temperatures.

Planes and Directions of Slip in the Face Centered Cubic Lattice—In the face centered cubic metals only the planes of closest atom packing, the octahedral planes $\{111\}$, function as slip planes and the slip occurs in the direction of one of the three cube face diagonals representing close packed rows of atoms on the given plane. Four families of octahedral planes are available for this purpose.

In single crystals under tension stress, slip starts on the set of octahedral planes for which the computed shear stress is a maximum, and continues on these planes until rotation of the lamellae brings an equal load on another set of octahedral planes. After a short period of extension by slipping on both sets of planes the crystal usually breaks with a wedge shaped fracture.

Pursuing the analogy with face centered cubic metals still further, hot rolling of iron above $1650^{\circ}\text{F}.$ might be expected to develop preferred orientation of the crystalline particles¹⁵ with the normal to a trapezohedral plane, $[112]$, approximately parallel to the direction of rolling and a dodecahedral plane $\{110\}$ parallel to the plane of rolling. Subsequent cooling below the A_3 point would produce some form of reorientation depending upon the relationship between the two sets of crystal axes established during the transformation. No accurate details of this process are yet available.¹⁶

Effect of Cold Work on the Properties of Iron

By Reid L. Kenyon* and Robert F. Mehl†

Introduction—The physical and mechanical properties of pure iron are given in another article in this Handbook.¹ The present article deals only with the effect of plastic deformation on these properties. Critical examination of the literature reveals that much of the published data on "pure iron" are actually on low carbon steel, sometimes with as much as 0.10% carbon and 0.50% manganese, besides other impurities. Due to the fact that few, if any, of the properties of pure iron can be extrapolated from such data, they are omitted from this article. While Armco Ingot Iron and electrolytic iron are not pure, they have been taken as such for the purpose of this tabulation. Since the few published results are from isolated tests, it is impossible to discriminate and select "best values." The data given here should be taken only as provisional, and as an indication of the need for further experimental work on the properties of plastically deformed pure iron.

The Effect of Cold Working

The previous mechanical and thermal history of the material, such as internal strain and grain size, has been found to have a marked effect on the response to cold working. Gries and Esser² give the results of Brinell tests on polycrystalline and monocrystalline iron after various degrees of cold rolling. Their values are reproduced in Fig. 1. The method of cold working also affects the results. Wire drawing produces a greater change than rolling for the same amount of reduction. Jeffries and Archer³ give tensile strength values for cold drawn Armco Ingot Iron wire, which are compared in Fig. 2 with cold rolled material. Greulich⁴ also reports the effect of cold rolling on the tensile properties of Armco Ingot Iron, but shows it to be considerably greater than normal, probably owing to a different previous treatment.

Various attempts have been made to express the properties of cold worked metals as functions of the percentage reduction. Greulich⁴ finds these relationships between reduction in thickness and hardness, yield point, and tensile strength to be logarithmic up to a limiting amount of reduction, but Templin⁵ shows that the tensile strength versus per cent reduction of area is a straight line. He gives the following equation for the tensile strength of Armco Ingot Iron: Tensile strength = 37,500 (1 + 1.64 R), where R is the fractional reduction of thickness. Greulich⁴ gives the equation: Tensile strength = 46,000 + 7,510 log. ϕ , where ϕ = the percentage reduction of thickness.

¹All references are given at the end of this article.

Templin's formula is believed to be in better agreement with most test data, although it should be remembered that all such particular relationships should be expected to apply only to material in the same initial condition. Their general application to pure iron in all conditions is doubtful.

A work hardening coefficient may be derived from Meyer's equation relating load and diameter of impression in the Brinell hardness test.⁷ In this equation, $p = a \cdot d^n$; the exponent n may be taken as a measure of the capacity of a material to work harden. Fig. 3 shows a series of such values for Armco Ingot Iron¹² cold rolled up to 57%. It will be seen that n decreases with cold work as expected. The slope of the true stress tensile curve is much used in Germany as a measure of rate of work hardening,^{8,9} but doubt has recently been expressed⁴ as to its usefulness, owing to the fact that this slope often is a constantly changing quantity. (See Stead¹⁰ and O'Neill and Greenwood¹¹ for additional studies on true stress curves).

The effect of cold working on the shape of the tensile stress-strain curve for Armco Ingot Iron is shown in Fig. 4. The disappearance of the yield point, increase of the tensile strength, and loss of ductility are the most noticeable effects. The curves in Fig. 4 are for specimens tested immediately after cold rolling; aging at room temperature or at slightly elevated temperatures alters these curves profoundly.¹²

The effect of cold work on the density is given elsewhere.¹ The electrical conductivity and magnetic properties are adversely affected, but no data have been found for high-purity iron.

Structure — The first visible effect of cold plastic deformation on the microstructure of iron is the production of slip bands on a polished surface. If the deformation is carried to a sufficient amount, the grains become distorted and elongated, and this appearance, unlike slip bands, is not changed by repolishing and reetching. This effect can only be detected after considerable cold reduction.

Macroscopically, iron exhibits, on fairly smooth or polished surfaces, a peculiar phenomenon that has been variously designated: Hartmann, Lüders, flow-lines, "worms," and "stretcher strains."^{13, 14, 15} The formation of these markings is associated with the behavior of iron at the yield point (sharp yield point with a definite amount of yield point elongation).⁴ When formed in tension, these markings are surface depressions resulting from local yielding; when formed in compression, they are local elevations on the surface. Deformation does not produce these markings on iron which has been previously cold worked an amount sufficient to prevent a sharp yield point (Fig. 4).

Sudden or impact deformation produces the so-called impact twins or Neumann bands. These twins differ from twins in face-centered metal in that they frequently exhibit irregular or serrated outlines; apparently iron forms no strain-anneal twins.

The mechanical properties of plastically deformed iron change with time after cold deformation when the material is held at room temperatures and at a more rapid rate at slightly elevated temperatures. This is called "aging" and is readily observed from the ordinary physical tests as a progressive increase in yield point, tensile strength, and hardness and decreases in elongation, reduction of area, and notch impact value,^{16, 17} which occurs slowly at room temperature and with increasing rapidity as the temperature is raised. At about 350°C. the effect begins to decrease, until at a sufficiently high temperature the effect can no longer be found. With increasing time these changes go through a maximum, beyond which the direction of the change is reversed. The time required for attainment of this maximum (or minimum) varies and becomes less as the temperature increases.¹⁸

Fig. 4—Effect of cold rolling on the shape of the stress-strain curve of Armco Ingot Iron (Kenyon and Burns⁴).

Fig. 5—Effect on the yield point of aging electrolytic iron (Ludwik and Scheu¹³).

Plastic deformation of a sufficient amount eliminates the sharp yield point from the tension stress-strain curve when the test is made immediately, but this yield point is made to reappear by aging a long enough time at the particular temperature. This is shown for electrolytic iron in Fig. 5. Köckritz¹⁸ shows (in Fig. 6)

Fig. 6—Increase in yield point and tensile strength of various steels resulting from cold stretching 5% and heating for 1 hr. at the indicated temperature (Köckritz).

the increase in tensile strength and yield point of Armco Ingot Iron in comparison with other materials.

The aging capacity is not exhausted by small amounts of plastic deformation. The total effects may be built up by successive aging treatments, plastic deformation, and heating at temperatures¹⁹ below the blue brittle range (250–300°C.).

The behavior of iron plastically deformed at room temperature and aged at temperatures in the blue brittle range is duplicated in kind, though in somewhat different degree, by simple plastic deformation in the blue brittle range. Since at this temperature the rate of aging is very great, the resulting increase in strength values and decrease in ductility values manifest themselves during the tensile test on previously unstrained material. This has been shown by Jeffries and Archer¹⁹ and Kenyon²⁰ for Armco Ingot Iron. Fig. 7 is reproduced from the latter source. The temperature ranges for these maxima and minima change somewhat with testing speed; higher speeds tend to throw them to higher temperatures.

When plastically deformed iron is heated to various temperatures, the properties are altered. The amount of the change depends on the amount of cold deformation, the original condition (such as grain size) and the time and temperature of heating after cold working. These changes do not all take place at one temperature but are progressively greater as the temperature is raised, although there is a minimum temperature below which the changes are relatively small. The magnitude of these changes is increased if recrystallization occurs.²¹ According to Sato,²² the increased energy introduced during cold deformation is released at approximately 570°C. Tammann²³ shows a gradual decrease in electrical resistivity and thermoelectric force with increasing temperature of annealing, whereas the magnetic susceptibility remains unchanged up to about 750°C., at which temperature it suddenly increases.

Annealing of cold worked iron has a pronounced effect on the mechanical properties as determined at room temperature. Published data are almost exclusively for steels, the only results found for pure iron being those for Brinell hardness as reported by Tammann.²³ Under suitable conditions of grain size, amount of deformation, and annealing time and temperature, these changes in mechanical

Fig. 8—Recrystallization of iron.

Annealing of cold worked iron has a pronounced effect on the mechanical properties as determined at room temperature. Published data are almost exclusively for steels, the only results found for pure iron being those for Brinell hardness as reported by Tammann.²³ Under suitable conditions of grain size, amount of deformation, and annealing time and temperature, these changes in mechanical

properties are accompanied by a profound change in grain size. The metal undergoes *recrystallization*. It is possible, however, to soften cold worked iron without causing recrystallization.²⁰ The behavior of iron with respect to recrystallization is represented conveniently, though inadequately, by a three dimensional diagram relating to degree of cold work, temperature of heating, and resultant grain size. Fig. 8 is taken from Oberhoffer and Oertel²¹ and represents the general relationships, although it is believed that there is a critical temperature range that leads to the extreme grain growth, varying with the amount of deformation. The curve on the basal plane shows the amount of strain required to cause recrystallization at a given temperature and indicates that this may occur as low as 400°C. McAdam²² shows Armco Ingot Iron to recrystallize, under certain conditions, at 485°C. It is known that factors not represented in Fig. 7 affect recrystallization. Thus, the initial grain size is an important factor, small grains requiring less overstrain (as measured by changes in dimensions) to initiate recrystallization than large grains. Time of heating is also important, as well as rate of heating if this is slow. Type of deformation also affects the results, though it is probable that these may be shown to be equivalent upon the basis of a common unit for expressing the amount of deformation. It is also believed that the effective deformation of the individual grains is greater with small than with large grains for a given amount of total change in dimensions of the piece so that effect of grain size may be due principally to this difference in effective deformation.

Wrought Iron

By A. W. F. Green*

Definition—Wrought iron is a ferrous material, aggregated from a solidifying mass of pasty particles of highly refined metallic iron with which, without subsequent fusion, is incorporated a minutely and uniformly distributed quantity of slag.

Manufacturing Terms—A number of terms particularly applicable to wrought iron and the products manufactured from it are as follows:

Puddled Ball—The agglomerate cellular mass of refined iron intimately mixed with a siliceous slag, which is the result of hand puddling, mechanical puddling, or the pouring of molten refined iron into a siliceous slag as in the Aston or Byers' process.

Bloom—The product resulting from the squeezing of the "puddled ball".

Muck Bar—Bar rolled from a squeezed bloom.

Bushelling—The process of heating to a welding heat in a suitable furnace, miscellaneous iron, steel or a mixture of iron and steel scrap cut into small pieces. (The welded mass is then squeezed into a bloom and rolled into scrap bar for piling or fagoting.)

Fagoting—The making of a "fagot" or "box", the bottom and sides of which are formed of muck or scrap bars and the interior of miscellaneous iron scrap or a mixture of iron and steel scrap (Fig. 1).

Fig. 1—Typical fagot for wrought iron (left). Fig. 2—Typical box pile (right).

Slab Pile—A pile built up wholly of flat bars of iron, all bars running the full length of the pile.

Box Pile—A pile of bars, the outside of which is formed of flat bars and the interior of a number of small bars, all running the full length of the pile. Used in the manufacturing of wrought iron bars (Fig. 2).

Refined Bar Iron or Refined Wrought Iron Bars—Iron bars rolled from a muck bar pile or from a box pile, of muck bars and wrought iron scrap free from steel, all bars running the full length of the pile (Fig. 3).

Double-Refined Iron—Iron to be classed as double refined shall be all new wrought iron, which shall be first rolled into muck bars. These bars shall then be

*Metallurgist, Allegheny-Ludlum Steel Co., Watervliet, N. Y.

twice piled and rolled. All iron shall be free from steel and from foreign scrap. The manufacturer may use his own mill products of at least equal quantity, but only in the first piling. In the final piling all bars shall be of the full length of the pile (Fig. 4).

Common Iron—Iron made from re-rolled scrap iron or a mixture of iron and steel scrap, no attempt being made to separate the iron and steel scrap (Fig. 5).

Methods of Manufacture—There are five methods employed for the making of wrought iron: 1. Hand puddling; 2. mechanical puddling; 3. the Aston or Byers, process; 4. bushelling; and 5. fagoting.

Hand Puddling Process—Wrought iron was in early times produced direct from the ore by reduction with carbonaceous fuel. In later times it has been produced by a variety of processes, usually however by indirect means. That is, the ore is first reduced to pig iron and the pig iron then transformed to wrought iron by the puddling or other process.

Fig. 3—Refined iron, macro etched. Fig. 4—Double refined iron, macro etched.
Fig. 5—Common iron, macro etched.

Henry Cort of England is credited with the inventions of the reverberatory type of furnace for the production of puddled wrought iron. The date given this invention is 1784. With only slight modification, the process has come down to the present day, and is commonly referred to as hand puddling.

The hearth of the hand puddling furnace is saucer shaped, and the lining is of sand. Iron oxide in the form of roll scale, iron ore, furnace cinder, or combinations thereof, is fettled into the sand bottom and sides of the hearth preparatory

to charging of the metal for puddling. The usual charges consist of pig iron. If a battery of furnaces is operated, it is often the practice to charge several different grades of pig iron, each furnace or portion of a battery of furnaces using a single type.

Heat is applied to the charge until it becomes molten. When molten, iron oxide in the form of roll scale, iron ore, furnace cinder, or combinations thereof, are added to the bath, which together with the siliceous oxide making up the bottom and sides of the hearth set up the refining action, tending toward the elimination of manganese, silicon, sulphur, phosphorus, and carbon. The first boiling period is called the low boil during which much of the manganese and silicon especially are eliminated from the metal. As the temperature of the bath rises due to the reaction, violent elimination of carbon begins and the period of the high boil takes place. During this time long blue carbon flames are expelled from the bath called the "Puddler's Candles". Necessarily, as the carbon is expelled, the melting point of the bath is raised and heat is actively generated in the furnace to maintain the bath molten and complete the reactions. The final stage is marked by the gradual freezing of the bath in the form of tiny iron particles called the *graining period*, at which time agitation is resorted to. The temperature of the furnace is no longer sufficient to keep the metal bath molten, although the siliceous slag having a much lower melting point, remains very liquid. The grained iron is gradually gathered into spongy balls and worked with the slag until sufficiently compact for removal to the squeezer. It is often necessary to drain excess slag from the furnace during this compacting operation, and on the other hand, siliceous slag forming ingredients must sometimes be added to further the welding and fluxing of the pasty iron particles.

The puddler determines the correct moment for removing the ball to the squeezer. The ball is a spongy mass of white hot iron dripping with slag. The squeezing and pressing operation further compacts the ball and ejects from it much of the excess slag it contains. The squeezed ball is then rolled into muck bars, billets, blooms, or other suitable shapes for reworking purposes.

Mechanical Puddling—The earliest efforts along the lines of mechanical puddling were to retain the furnace as it existed, and to substitute mechanical for manual power in manipulating the rabblers or stirring rods. The early developments which showed the most promise centered about the use of revolving furnaces. These were of three types: 1. Those having a variable axis of revolution; 2. those having an approximately vertical axis; and 3. those having a horizontal axis.

The Godfrey-Houson puddler was the best example of the first type. The Pernot furnace was probably the best example of the second type, and the Spencer, Menelaus, Danks, Crompton, and Ely inventions the best of the third type. The Ely furnace was used for puddling as late as 1934. Generally speaking, the horizontal type of revolving furnace succeeded in reducing the manual labor of puddling and balling and possessed the important feature of working on a hot bottom.

The mechanical and physical reactions encountered in mechanical puddling procedures are virtually the same as those in the hand puddling procedure. Some idea of what some of these inventions meant in increasing production of wrought iron may be gathered by these comparisons: The manual puddler produced balls weighing from 200-250 lb. each, and his entire output was approximately 2800 lb. per day. Each manually operated furnace had a fireman, a puddler's helper, and a puddler. The Ely rotary type of furnace which was oil fired, made balls averaging about 750 lb. each. One operator with two helpers managed two furnaces. Using molten iron from a cupola, these two furnaces produced 22,000-22,500 lb. of wrought iron in 8 hr. The Roe puddler on the other hand, can produce an 8000-10,000 ball or bloom using molten iron direct from the blast furnace every 60 min.

The Aston or Byers Process—The most startling invention having to do with the making of wrought iron is what is known as the Byers or Aston process. The work which resulted in this invention started about 1918 and constituted the most outstanding development in the manufacture of wrought iron since Cort's invention of the use of the reverberatory type of furnace early in the 18th century. The Byers or Aston process is of a far different nature than puddling either by hand or mechanical means. The melting of metal is done in cupolas. The molten

metal is then carried in suitable ladles where it is desulphurized and immediately thereafter, poured into Bessemer converters where it is refined according to regular steel procedure. Silicon, manganese, and carbon are oxidized in this refining operation. The blown metal is then tapped into a ladle and taken to the processing platform where it is poured into the ladle of the processing machine. The molten refined iron is poured at a predetermined rate into the ladle containing the molten slag. As the slag temperature is maintained several hundred degrees lower than the freezing point of the refined metal, the latter is continuously and rapidly solidified. This rapid solidification of the metal liberates its dissolved gases with sufficient force to shatter the metal into small fragments which settle to the bottom of the ladle. Due to the heating temperature and fluxing action of siliceous slag, these fragments weld together to form an agglomerate cellular mass in the form of a sponge. Immediately upon completion of the pour, the ladle is transferred and excess slag is poured off into an adjoining empty ladle. The sponge ball, weighing from 6,000-8,000 lb., is dumped at the rate of one, every five minutes on a platform of a 900-ton electrically driven press, where it is squeezed, collecting the mass into solid blooms for rolling.

Squeezing—There are three types of squeezers used for compressing the sponge balls into suitable shape for rolling into muck bar, bloom or billet sizes. The first is the small so-called coffee mill type, the drum operating on a vertical axis. The second, a generally larger type, except that the drum operates on a horizontal axis. The third, the steam, electric or hydraulic press types where pressures are applied on the ends as well as on the four sides of the ball.

Physical Properties

Sp.gr.	7.70
Melting point	2750°F.
Coefficient of thermal expansion—18-100°C.....	11.40 $\times 10^{-6}$
Heat conductivity—18°C.....	0.152
18°C.....	0.144
100°C.....	0.143

Chemical Analysis—Genuine wrought iron is identified because of its low carbon and manganese contents. Many specifications written to cover wrought iron analyses lay particular stress on the manganese content. It is generally conceded that freedom from contamination by steel or poor quality wrought iron can be shown if the manganese content is under 0.07%. Some typical chemical analyses are shown in Table I.

Table I
Typical Composition of Wrought Irons

Type of Iron	C	Mn	Si	P	S	Slag by Weight
Byers No. 1.....	0.08	0.015	0.158	0.062	0.010	1.20
Mechanical iron	0.08	0.029	0.183	0.115	0.015	2.85
Hand puddled iron . . .	0.06	0.045	0.101	0.068	0.009	1.97

Carbon—A carbon content over 0.10% is usually construed to mean imperfect refining, or awakens the suspicion that steel scrap has been used in making up the customary "piles".

Manganese—Well made wrought iron has a manganese content below 0.10%. If in excess of that amount imperfect refining may be indicated, or adulteration by use of steel in bushelling or piling.

Phosphorus—The phosphorus content of wrought iron is largely in the incorporated slag. Good wrought iron will contain from 0.08-0.160%, of which from 40-60% will be combined with the slag.

Sulphur—High grade wrought iron contains up to 0.035% sulphur. Higher amounts are known to produce "red shortness" and also indicate imperfect refining.

Silicon—The amount of silicon is usually from 0.10-0.20%. The proportion associated with the base metal is practically nil. Silicon under 0.10% indicates either that there is not the normal amount of slag, or that the composition of the slag is not normal for properly refined wrought iron. Silicon content about 0.20% may indicate poor slag distribution, probably due to improper mechanical working.

Slag—There is present in wrought iron a considerable amount of slag. A typical analysis of the slag found in wrought iron is as follows: SiO_2 , 14.58; Fe, 58.72; FeO , 70.49; MnO , 1.51; Al_2O_3 , 2.72; CaO , 2.59; P_2O_5 , 0.80; S, 0.08; Cu, trace; and Fe_2O_3 , 5.65. The amount of slag present in wrought iron by weight varies from 1 to as much as 4%, generally about 2.00%.

Alloy Wrought Iron—The most prominent of the alloy wrought irons are those containing nickel up to about 3½%. Molybdenum has been successfully alloyed and nickel and molybdenum together have been used. Copper is often found in wrought iron. It is possible to definitely alloy quantities of copper in the making of wrought iron. There is a question regarding its presence as to whether or not it has a deleterious effect on the red shortness characteristic. Numerous experiments have shown, however, that it does not materially affect this condition with percentages up to about 0.3% and it is entirely possible that its presence is desirous from the standpoint of corrosion. Nickel up to 3½% materially raises the elastic limit and tensile strength. Molybdenum does not seem to have any material effect on physical properties, and no concise data has been found to show that its presence has materially affected the general quality of wrought iron. An analysis of nickel wrought iron is as follows: C 0.06, Mn 0.035, P 0.070, Si 0.18, S 0.011, Ni 3.25, and slag 1.90.

Forging and Welding Ranges—The proper hot working or forging range is 2450-1650°F. However, the most reduction in forging should take place between 2450-2175°F.

The proper welding range is 2450-2300°F.

Tensile Properties at Low and High Temperature—The tensile properties of wrought iron without nickel are as follows: Tensile strength, psi., 42,000-52,000; yield point, psi., 26,000-35,000; elongation, per cent in 8 in., 25-40; and reduction of area, 40-55%.

When nickel is added to approximately 3.25-3.50% the values are about as follows: Tensile strength, psi., 55,000-60,000; yield point, psi., 45,000-50,000; elongation, per cent in 8 in., 25-30; and reduction of area, 35-45%.

Results of tensile tests at high temperatures are given in Fig. 6.

Bend Tests—Bend tests are resorted to in the testing of wrought iron to indicate not only the ductility but also quality, proper piling and freedom from adulteration with steel. These tests are made both hot and cold and also by nicking of cold bars.

Hot bend tests on highest quality wrought iron require bending the sample flat on itself from a temperature of 1700-1800°F. The poorer qualities of wrought iron are bent around a pin, equal in diameter to the diameter or the thickness of the bars being tested. It is sometimes required that hot bend tests be made at temperatures of 1400-1500°F. to determine whether or not the iron is "red short", a not uncommon condition.

Step Tests—The step test is applied to wrought iron to show that material is free from large slag inclusions as well as to determine methods of piling and contamination with steels. The bar as machined for the various steps is shown in Fig. 7.

Crush Tests—It is generally possible to tell the difference between galvanized wrought iron and galvanized steel by bending or flattening cold. If the zinc coating adheres firmly, the material is usually wrought iron. If the zinc starts to scale off at the beginning of the test the material is steel.

Pickling—The usual procedure for pickling of wrought iron pipe, rods, and bars, is to use a 4-5% solution of sulphuric acid at a temperature of 160-170°F. The pickling time for pipe varies from 1-1½ hr. and the rods or bars, 30-45 min.

Fig. 6—Tensile tests of wrought iron at high temperature.

After pickling, material should be washed in water, and then passed through a bath of $\frac{1}{2}\%$ caustic soda and $\frac{1}{4}\%$ trisodium phosphate by volume.

Carburizing—Wrought iron can be case hardened. The usual process is to pack the parts in suitable compounds and quench in water from the box, or cool in the box and reheat to a suitable temperature and then quench in water.

The type of iron to be case carburized should be selected carefully since best results are obtained from iron made from box piles. The temperatures for carburizing and hardening are much the same as would be used for S.A.E. 1010 steel.

Protective Coatings—Protective coatings adhere firmly to wrought iron. This is to be expected because of the nature of the material. Fig. 8 shows the bonding

Fig. 7—Step test.

of a galvanized coating to wrought iron as compared with ordinary steel. In general, any protective coating that is applied to steel, except electropickling, can be applied to wrought iron.

Welding—The ease with which wrought iron can be welded is attributed to the relative purity of the base metal and the siliceous slag which confers on it a self-fluxing quality easily observable in hammer and pressure welds. The slag content of wrought iron makes it self-fluxing so uniform strong welds are rapidly secured.

Wrought iron lends itself readily to oxy-acetylene and arc welding. A fluxed or greasy surface is ordinarily an indication that the temperature

Fig. 8—Bonding of a galvanized coating to wrought iron and steel.

is sufficiently high to start applying fused secondary or weld rod metal. This is not quite true of wrought iron where a greasy appearance initially occurs due to the self-fluxing characteristic at a somewhat lower temperature. The temperature at which wrought iron fluxes is below the actual fusion point of the base metal and is too low for the application of the secondary metal. The welding should, therefore, be continued and the temperature of the edges where welding is to take place, raised somewhat higher. In this connection it should be remembered that wrought iron can stand higher heat without damage than other ferrous metals, and in general, should be worked hotter for best results.

Resistance to Corrosion—Wrought iron has demonstrated through centuries of application a remarkable resistance to progressive corrosion. The reason

for this is primarily the slag content and its distribution throughout the mass. Where wrought iron is exposed to corrective media, it is quickly coated with a film

of oxide or rust. As corrosion proceeds additional oxide is formed but the slag filaments begin to function as rust resisters. The initial oxide film is securely fastened to the surface of the metal by the pinning effect of the slag filaments thus serving to protect the metal from further oxidation.

It should not be taken to mean that all grades of wrought iron demonstrate the same properties of resistance to progressive corrosion. Bushed and fagoted iron, especially the types known as common iron, do not possess to any remarkable degree such property. Resistance to progressive corrosion is limited entirely to genuine wrought iron which has not suffered by adulteration through working.

Repeated Stress—From the point of view of laboratory tests alone, wrought iron is about the weakest ferrous material under repeated stress. The endurance limit of wrought ferrous metals determined in reversed or rotary bending is, in the absence of corrosion, about half of the tensile strength. Moore gives the following endurance limits in rotating beam and axial loading tests.

Materials	Endurance Limit, Rotating Beam, psi.	Axial, psi.	Tensile Strength, psi.	Charpy Notched Bar, ft.-lb.	Brinell Hardness No.
Wrought iron, longitudinal.....	23,000	16,000	46,900	17.5	105
Wrought iron, transverse.....	19,000	11,000	34,400	4.8	105
Ingot iron, as rolled.....	26,000	17,000	42,400	19.3	69
Structural steel, C 0.18% (as rolled)....	28,000	61,500

Wrought iron is not materially handicapped in fatigue resistance by the presence of slag as long as the applied stress is longitudinal.

Izod Value for Wrought Iron

(Longitudinal Test. Average of 3 Tests)

Kind of Iron	Original Size	Izod Values, ft.-lb. "A" Notch at Right Angles to Flat Plane of Piling; "B" Notch at 90° to "A"	"A" "B"
Staybolt	1 in. rd.	45	44
Enginebolt	1 in. rd.	41½	42
A.S.T.M. 84-27C	1 in. rd.	44½	53
Bushed iron.....	1 in. rd.	51½	56
Bushed iron.....	1 in. sq.	51½	65
Bushed iron.....	2 x ½ in. flat	58½	58½
Common iron.....	1 in. rd.	63½	70
Common iron.....	1 in. sq.	62½	71
Common iron.....	2 x ½ in. flat	43	51

Applications and Forms Available—Wrought iron is used by the railroads, by shipbuilding industries, oil industries, for architectural use, by the public utilities, on farms, and for farm implements.

Wrought iron is available in blooms, billets, in all types of hammered bars and forms, and hot rolled shapes, including sheets and plates. Also, as wire for nails and barb wire manufacture and wire for general manufacture.

Weight of Wrought Iron—In calculating the weight of wrought iron bars and shapes, it is common practice to use the usual tables applicable to steel and deduct 2% from the weight shown in such tables.

Market Prices for Wrought Iron Products (May, 1936)

Cents Per Lb. Base

Some typical present-day prices for wrought iron are as follows:

Staybolt iron to meet A.S.T.M. Spec. A-84-33.....	6.25
Enginebolt iron to meet A.S.T.M. Spec. A-84-33.....	5.20
Single refined enginebolt iron (all new, no crop ends, all pieces full length of the pile).....	3.50
Single refined enginebolt iron (½ new puddled iron and ½ crop ends of equal quality).....	3.20
Refined wrought iron to meet A.S.T.M. Spec. A-41-30.....	2.30
Double refined wrought iron to meet A.S.T.M. Spec. A-41-30.....	4.24
Common iron to meet A.S.T.M. Spec. A-85-27.....	1.65

Alloys of Iron and Nickel With Low Expansion Coefficients

By Dr. Matthew A. Hunter*

General Introduction—Alloys of iron and nickel possess many anomalous properties, depending on the relative proportions of the two constituents in the alloy. Guillaume discovered the alloys of low linear coefficient of expansion. In an intensive investigation of a series of various compositions, he found coefficients of linear expansion ranging from a small negative value (-0.5×10^{-6}) to a large positive value (20×10^{-6}). The alloy with 36% Ni with minor constituents of Mn, Si, and C, amounting to less than 1% had so low a coefficient of expansion that its length was practically invariable for ordinary changes in temperature. For this reason Guillaume gave the alloy the name "Invar."

Subsequently in the work of Guillaume and Chevenard, in cooperation with the Societe de Commentry-Fourchambault, an intensive study was made of the thermal and elastic properties of this class of alloys. Alloys with higher contents of Ni were found to possess higher coefficients of expansion. The alloy with 39% Ni had a coefficient of expansion corresponding to that of the low expansion glasses. The 46% alloy had a coefficient equivalent to that of platinum (9.0×10^{-6} per °C.) and received the name Platinite. A 42% nickel alloy when covered with copper to prevent gassing at the seal, is known as Dumet wire and is used to replace platinum as the "seal in" wire in incandescent lamps, and vacuum tubes. The 56% alloy

has a coefficient approaching that of ordinary steel (11×10^{-6} per °C.). Nilvar is identical with Invar (36% Ni).

In studying the elastic properties, Guillaume disclosed the alloy Elinvar, containing 36% of Ni and 12% Cr, which possesses an invariable modulus of elasticity over a considerable range in temperature as well as a low thermal expansivity.

Alloys containing less than 36% Ni have materially higher coefficients of expansion. The 18% Ni alloy has an expansion coefficient of 20×10^{-6} . These alloys belong in the irreversible class and by reason of their high coefficients are excluded from the present category.

Fig. 1—Effect on the coefficient of linear expansion at 20°C. for nickel-iron alloys (0.4% Mn and 0.1% C) (Guillaume).

Fig. 2—Displacement of minimum expansivity by the additions of other metals (Guillaume).

Fig. 3—Change in minimum expansivity caused by additions of other metals (Guillaume).

Fig. 4—Change in length (ΔL) with temperature T of a typical Invar (Guillaume).

It has recently been found that certain percentages of cobalt can be used with advantage to replace Ni in the 36% alloy. An addition of 5% cobalt gives an alloy with an even lower coefficient than Invar and one less susceptible to variations in heat treatment.

Effect of Composition on Expansivity—The effect on the linear expansivity of variations in Ni content is given in Fig. 1.

The minimum expansivity occurs at about 36% Ni. A considerable influence is exerted on the position of this minimum expansivity by minor additions of other metals. The effect of additions of Mn, Cr, Cu, or C is shown in Fig. 2.

Minimum expansivity is shifted toward higher contents of Ni in the case of Mn and Cr and towards lower contents of Ni in the case of Cu and C. The minimum expansivity for any of these ternary alloys is, in general, greater than that of a

*Consulting Engineer, Driver-Harris Co., Harrison, N. J., and Prof. of Metallurgical Engineering, Rensselaer Polytechnic Institute, Troy, N. Y.

typical Invar. The extent of the variation caused by these additions is given in Fig. 3.

Additions of silicon, tungsten or molybdenum produce effects similar to that of manganese and chromium—the minimum is shifted towards higher contents of Ni. Carbon is said to produce instability in Invar. Guillaume attributes this to the changing solubility in the austenitic matrix under heat treatment.

The replacement of some of the nickel by cobalt (up to 8%) produces a lowering in the expansivity of the alloy.

Physical Properties, Expansivity—It is not generally recognized that the low

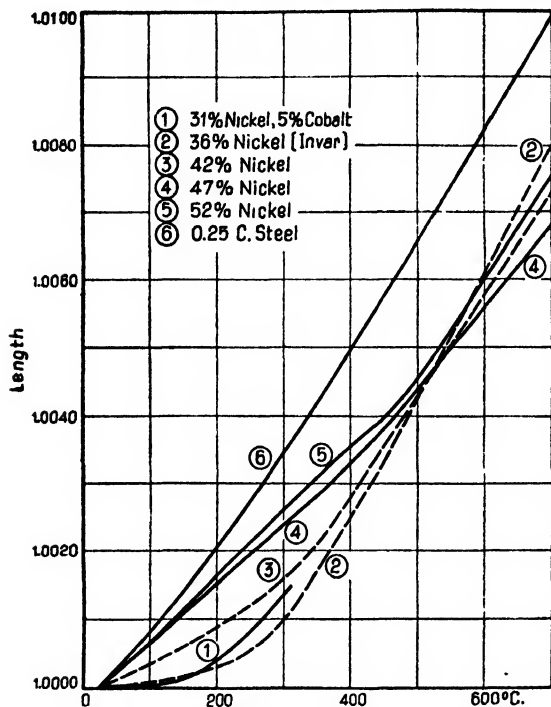

Fig. 5—Expansion of nickel-iron alloys (Hunter).

of the curve between C and D is then a measure of the coefficient of expansion over a limited range of temperature. The following figures are given by Guillaume for the coefficient of linear expansion between 0 and 38°C.

Expansion of Nickel Steels

% Ni	Mean Coefficient $\times 10^{-6}$	% Ni	Mean Coefficient $\times 10^{-6}$
31.4	3.395 + 0.00885 t	43.6	7.992 - 0.00273 t
34.6	1.373 + 0.00237 t	44.4	8.508 - 0.00251 t
35.6	0.877 + 0.00127 t	48.7	9.801 - 0.00067 t
37.3	3.457 - 0.00647 t	50.7	9.984 + 0.00243 t
39.4	5.387 - 0.00448 t	53.2	10.045 + 0.00031 t

Over wider ranges of temperatures the behavior of the alloys is represented by the curves given in Fig. 5. For purpose of comparison the expansion temperature curve for an ordinary steel is included.

Under the effect of heat treatment or cold work the values for the expansivity of Invar (or Nilvar) change considerably. The effect of heat treatment is shown in Table I by Russell.

The expansivity is greatest for well annealed material and least in the quenched samples.

Cold drawing also produces a lowering in the expansivity. The following coefficient figures are taken from the writer's own experience on two heats of Nilvar (Invar).

Effect of Quenching and Cold Drawing on Expansivity

Direct from the Hot Mill	Annealed and Quenched	Quenched and Cold Drawn Size 0.125-0.250 In.
1.4×10^{-6}	0.5×10^{-6}	0.14×10^{-6}
1.4×10^{-6}	0.8×10^{-6}	0.3×10^{-6}

Table I
Effect of Heat Treatment on Coefficient of Expansion

Treatment, °C.	Brinell Hardness	Mean Coefficient $\times 10^{-6}$	
After forging	142	17-100°C.	1.66
Quenched, 830	196	17-250°C.	3.11
Quenched 830, temp.....	250	18-100°C.	0.64
		18-250°C.	2.53
		15-100°C.	1.02
		15-250°C.	2.43
Heated to 830—19 hr., cooling to room temp.....	114	15-100°C.	2.01
		15-250°C.	2.89

It is possible by cold work following a quenching operation to produce material with a zero coefficient of expansion or even a negative one. In the latter case by careful annealing at a low temperature, the coefficient may be increased to zero again. These artificial methods of securing a low coefficient all tend to produce instability in the material. The low coefficients tend with the lapse of time and variations in temperature to recede to the normal values for the material. These "aging" tendencies are responsible for the secular and transitory changes which take place in the material. While these variations are of importance in special applications such as geodetic tapes, they are of little significance in ordinary operations. For such special applications it is essential to stabilize the material by submitting it to a slow cooling operation from 100-20°C. over a period of many months, followed by a prolonged aging at room temperature. But unless the material is to be subsequently used within the limits of the atmospheric variation in temperature, such stabilization is of no value.

Magnetic Properties—All nickel-iron alloys of the Invar class are magnetic at room temperature. They lose their magnetism at higher temperatures and become paramagnetic. The points of inflection in the curves in Fig. 5 are indications of the loss of magnetism. For a true Invar (36% Ni) Russell found that in a well annealed sample the loss of magnetism began at 162 and was completed at 271°C. In a quenched sample the loss began at 205 and was complete at 271°C.

Slow cooling through this range of temperature eliminates to a large degree the transitory and secular changes which are always troublesome in materials of this class.

Electrical Properties—The electrical resistivity of Invar ranges between 75 and 85 microhm cm. at ordinary temperatures. The temperature coefficient of electrical resistivity is of the order of 0.0012 per °C. over the low expansivity range. The thermoelectric power taken against copper is about 10 microvolts per degree.

Other Physical Properties—Sands has collected from various sources information on the miscellaneous properties of Invar from which the following are taken. The material was in the hot rolled or forged condition.

Melting point	1425°C. (2600°F.)
Density	8.0 g. per cc. (500 lb. per cu. ft.)
Tensile strength	65,000-85,000 psi.
Yield point	40,000-60,000 psi.
Elastic limit	20,000-30,000 psi.
Elongation	30-45%
Reduction in area.....	55-70%
Scleroscope hardness	19
Brinell hardness	160
Modulus of elasticity in tension.....	21,400,000 psi.
Thermoelectric coefficient	500×10^{-6} per °C.
Specific heat (25-100°C.)	0.123 cal. per g. per °C
Thermal conductivity (20-100°C.).....	0.0262 Cgs. units
Thermoelectric power (against copper), -96°C.....	9.8 microvolts per °C

The effect of temperature on the mechanical properties is shown in Fig. 6.

Processing—Considerable care has to be used in the hot working of these iron-nickel alloys, as they have a tendency to check and break up unless carefully handled. The annealing of Invar and related alloys should be done in a reducing atmosphere. These alloys are very susceptible to intercrystalline attack during annealing. The best results are, therefore, usually obtained by annealing in an atmosphere consisting of a large percentage of a neutral gas such as nitrogen and a small percentage of a reducing gas.

Fig. 6—Effect of temperature on the mechanical properties of forged 34% nickel-iron alloys (MacPherran).

Fig. 7—Upper Curve—Effect of nickel on the inflection temperature of nickel-iron alloys.

Lower Curve—Effect of nickel on the average coefficient of expansion up to the inflection temperature of nickel-iron alloys.

containing 31% Ni and 4-6% Co produces a material with a zero coefficient of expansion in the hot rolled condition. Annealing and quenching appear to raise the coefficient somewhat, but in general the coefficient obtained from these alloys is lower than that obtained from Invar without subjecting it to cold work. An extensive investigation of this class of alloys has been made by Masumoto.¹

The cold rolling and drawing of these iron-nickel alloys is quite similar to that of nickel.

Heat Treatment of Invar—The annealing temperature of 750-850°C. (1380-1560°F.) gives good results. Quenching in water from these temperatures reduces the expansivity of the material, but induces instability both in actual length and in linear coefficient. To overcome these defects and stabilize the wire, a low temperature anneal (200-300°F.) followed by slow cooling to room temperature over a period of months is necessary. Slow cooling through the magnetic transformation has also been found satisfactory.

Applications

Absolute standards of length.

Rods and tapes for geodetic work.

Compensating pendulums and balance wheels in clocks and watches.

Expansion control in moving parts, automobile pistons.

Thermostatic strip.

Other Iron-Nickel Alloys—Alloys of iron and nickel, with nickel contents higher than Invar, retain to some degree the expansion characteristics of metals of the Invar composition.

Since further additions of nickel raise the temperature at which the inherent magnetism of the alloy disappears, the inflection temperature in the expansion curve rises with the increasing nickel content. While this increase in range is an advantage in some circumstances, it is obtained at a sacrifice of the low coefficient of expansion itself.

Scott² has published information on the coefficient of expansion of iron-nickel alloys up to the inflection temperature. Lohr and Hopkins³ give data on a more extended range of nickel contents up to 68% as given in Table II and Fig. 7.

Special Alloys—Certain ternary alloys with nickel and iron are interesting by reason of their special properties.

Super Nilvar—The replacement of some of the nickel by cobalt in an alloy of the Invar composition results in a lowering of the linear coefficient of expansion of the alloy. An alloy produces a material with a zero coefficient of expansion in the hot rolled condition. Annealing and quenching appear to raise the coefficient somewhat, but in general the coefficient obtained from these alloys is lower than that obtained from Invar without subjecting it to cold work. An extensive investigation of this class of alloys has been made by Masumoto.¹

*Note that in alloys with higher than 55% nickel, the inflection temperature is not in evidence.

Iron-Nickel-Cobalt Alloys—Scott³ has investigated the expansion properties of a series of low expansion iron-nickel-cobalt alloys over a range of cobalt additions up to 40%. Such additions raise the coefficient of expansion at room temperature. But since they also raise the inflection temperature, they produce an alloy with a moderately low coefficient of expansion over a wider range of temperature. Scott expresses his observations in the form of equations. If θ is inflection temperature, X the nickel content, Y the cobalt content, Z the manganese content and W the carbon content, the inflection temperature of any alloy in the group studied is given by:

$$\theta = 19.5 (X + Y) - 22 Z - 0 W - 465$$

Introducing the restriction that the nickel and iron content shall be so related as to depress the A_r point to about -100°C . then:

$$Y = 0.0795 \theta + 4.8Z + 19W - 18.1$$

$$X = 41.9 - 0.0282 \theta - 3.7Z - 19W$$

for inflection temperatures between 200 and 600°C .

The expansivities obtainable with these compositions are given by:

$$\alpha_1 \times 10^6 = 0.024 \theta + 0.38 Z - 1.2 W - 6.65$$

$$\alpha_2 \times 10^6 = 0.024 \theta + 0.38 Z - 1.2 W - 5.6$$

the former representing minimum expansivity and the latter mean expansivity when θ comes between 350°C . and 600°C .

Applications of these alloys in relation to seal in wires in glass are given by Scott⁴ and Hull and Burger. Scott's alloy "Kovar" and Hull's alloy "Fenico" contain approximately 54% iron, 28% nickel, and 18% cobalt.

Iron-Cobalt-Chromium Alloys—Masumoto² has made observations on an alloy containing 36.5-37% iron, cobalt 53-54.5%, and chromium 9-10% which has an exceedingly low coefficient of expansion, at times negative over the range $0-100^\circ\text{C}$. An alloy in this class is suggested by Hull as a seal in wire in special glasses—Fenichrome—37% iron, 30% nickel, 25% cobalt, and 8% chromium.

Elinvar—In determining the thermoelastic coefficients of nickel-iron alloys, Guillaume found that Invar had the highest elastic coefficient of all the alloys in the related group. There were, however, 2 alloys at 29% and 45% Ni which had zero coefficient, that is, their modulus of elasticity did not change with variations in temperature. But since, in these alloys, small variations in the nickel content produced large variations in the elastic coefficient, the commercial application of

the discovery was a difficult one. He found that the addition of 12% chromium to an alloy containing 36% nickel produced an alloy which had zero thermoelastic coefficient and one which was not susceptible to small variations in Ni content, which are to be expected in commercial melting. To this alloy he gave the name "Elinvar."

It has a particular application in the construction of such articles as hair springs and balance wheels in clocks and watches and in tuning forks used in radio synchronization, where an invariable modulus of elasticity is required. It has the further advantage in such situations of being nonmagnetic and comparatively rust-proof.

The composition of this material has been somewhat modified from the original specifications. Shubrooks gives the following limits for the material as now used.

Nickel	33-35%	Manganese	0.5-2%
Iron	61-63%	Silicon	0.5-2%
Chromium	4-5%	Carbon	0.5-2%
Tungsten	1-3%

Corrosion of Iron and Steel

By T. S. Fuller*

The problem of corrosion is of the greatest interest to all producers and users of iron and steel and it is most desirable that all should have as comprehensive an understanding of the subject as possible.

Corrosion Theories—Corrosion was first considered to be a case of simple oxidation, similar to that taking place when iron is heated in air. It was soon discovered, however, that not only was the presence of oxygen necessary, but also the presence of liquid water.

This discovery led to the acid theory of corrosion¹ which takes into account the necessary liquid water and oxygen, and postulates, in addition to these, the presence of an acid, usually carbonic. The acid is assumed to unite chemically with the iron, forming a soluble ferrous salt, which is later oxidized to ferric hydrate or rust, liberating the acid radical for further attack upon the iron. By this method it is quite evident that very minute quantities of acid will be sufficient to cause corrosion.

In 1903, Whitney² announced the results of experiments which led to the electrolytic theory of corrosion. Distilled water was boiled in test tubes to expel all the air and CO₂; polished samples of iron were added and the tubes sealed while the water was boiling. These tubes were allowed to stand in this manner for weeks without the slightest appearance of rust on the surface of the iron or appearance of a corrosion product on the glass or in the solution. At the end of several weeks the tubes were opened and a small amount of air admitted. A precipitate of ferric hydrate quickly settled out. Whitney's interpretation of the results follows:

Iron goes into solution in pure liquid water until the water becomes saturated with iron ions and a state of equilibrium is established. Until oxygen is admitted no precipitation of iron takes place. The conclusion is reached that iron goes into solution in liquid water in the absence of both an acid radical and oxygen and that corrosion is, therefore, essentially an electrolytic phenomenon. When the iron is dissolved by the water it first forms ferrous hydroxide, Fe(OH)₂, but due to its solubility it is not noticeable until a further reaction with oxygen takes place.

The ferric hydroxide, Fe(OH)₃, settles out of the solution as a reddish-brown precipitate and gradually passes to hydrous ferric oxide, Fe₂O₃, which is commonly known as rust.

These reactions will not take place in dry air or water free from oxygen, but as ordinary water always contains some dissolved oxygen corrosion will always take place when iron or steel is exposed to moist air.

The hydrogen peroxide theory³ postulates the presence of this substance as an intermediate product in the formation of rust and the biological theory⁴ regards the corrosion of iron as a phenomenon due primarily to micro-organisms.

The acid and electrolytic theories are of chief interest to students of corrosion. It is a difficult matter to say which of these two views is correct because of the difficulty of getting extremely pure substances to work with, but it is safe to say that 90% of the students of the corrosion of iron prefer to regard it as an electrochemical phenomenon.

Considerable impetus was given to the study of corrosion by experiments of Whitney, which led to the electrolytic theory. Later Cushman and Walker developed a reagent which became known as ferroxyl indicator, which demonstrates quite clearly the nature of ferrous corrosion.

The indicator has been described in detail by Cushman.⁵ Briefly, it may be prepared by mixing dilute water solutions of phenolphthalein and potassium ferricy-

⁵A. S. Cushman and H. A. Gardner, *Corrosion and Preservation of Iron and Steel*, 1910.

anide. If a more or less permanent record is desired, the solution is thickened with gelatin or agaragar. The action of the ferroxy indicator is this—a solution containing phenolphthalein becomes pink in the presence of an excess of hydroxyl ions; potassium ferricyanide in the presence of ferrous ions gives a dark blue precipitate. Therefore, with the indicator in contact with an iron surface, the positive areas—for example, points where iron is going into solution in the ferrous condition—are colored blue, and the negative areas, where there is a predominance of hydroxyl ions, are colored pink by these ions.

Corrosion Rate—The rate of corrosion of every piece of iron or steel depends upon the individual conditions existing in the particular locality in which the metal is in use, as well as upon the means which have been taken to prevent corrosion.

Bearing in mind that the two substances besides iron necessary for ferrous corrosion are liquid water and oxygen, corrosion phenomena are of many types. Iron samples, wholly immersed, corrode faster if the water is moving rapidly than they do if it is in a state of rest. The rate of corrosion of iron tanks or pipes holding water is much less if they are kept full than if they are alternately wet and dry. Atmospheric corrosion proceeds much more rapidly in districts where the atmosphere is chemically polluted by sulphur vapors and the like than it does in districts where the atmosphere is free from contamination. The corrosion of iron or steel is accelerated or retarded by contact with other metallic elements, depending on whether the elements are electro-positive or electro-negative with respect to iron. The corrosion rate increases with rising temperature.

The rate of corrosion is also dependent upon the character of the steel as determined by its chemical composition and heat treatment. Stainless steel with large amounts of chromium and the various alloys of nickel, chromium, silicon and iron are highly resistant to corrosion.

The chemical and structural compositions of iron and steel vary throughout the mass and because the various constituents have different electrical potentials, corrosion may be either accelerated or retarded thereby. The different electrical potential thus developed is usually comparatively great in badly segregated iron and steel or in metal containing impurities, all of which accelerate the corrosion.

Recent work of U. R. Evans emphasizes the influence of protective films upon the corrosion rate.

Stainless Steels—Because of their high corrosion resistance considerable quantities of alloy steels containing large amounts of chromium, and chromium and nickel have come into general use. The most common of these are the ones containing 14% of chromium, and 18% of chromium and 8% of nickel. The former alloy can be heat treated to give excellent physical properties varying over a wide range; the latter is austenitic in structure, and therefore cannot be heat treated to give specific properties, those properties being imparted only by the hot and cold working process. For maximum corrosion resistance it is necessary that both alloys shall have been heated and cooled in such a manner as to leave the carbides in solution.

Protective Coatings—Protective coatings for iron and steel form an important section of metal technology, and may be grouped under the following headings: 1. Paints; 2. metal coatings; 3. chemical coatings; and 4. greases.

Paints—Various specially prepared paints are used for protecting the surface of iron and steel. The paint must protect the surface from dampness, such as sea water, oxidizing gases, and smoke. Therefore no one paint is suitable for all purposes, and before a paint is applied the nature of the corrosive influence present must be determined.

Some paints protect the surface merely by the formation of an impervious film, such as asphaltum and tar. Other paints exert a chemical protective action, such as the ones containing linseed oil as the vehicle, and red lead as the pigment. The linseed oil absorbs oxygen from the atmosphere and by so doing forms a thick elastic covering. This reaction is hastened by boiling the linseed oil before using and adding salts of manganese or lead, which are called driers.

A few of the pigments used in paints are red lead, oxides of iron, lead sulphate, zinc sulphate, graphite, and hydrocarbons. The driers, vehicle, and pigments used must be inert to the steel; otherwise corrosion will be hastened instead of prevented.

Metal Coatings—The metal coatings include hot galvanizing, Lohmannizing, Sherardizing, hot tin dip, and electrolytic plates of tin, nickel, copper, and cadmium.

Galvanizing—Galvanizing is a process for coating metal with a thin layer of zinc. When the galvanized object is exposed to corrosive action, the zinc is dissolved in preference to the iron because it is more electro-positive.

The object to be galvanized is dipped in a bath of molten zinc (hot galvanizing) at a temperature about 810-840°F. In electro-galvanizing (cold galvanizing) the object to be coated with zinc is immersed in a bath containing a zinc salt as the electrolyte. The object to be coated is attached to the negative electrode and the metallic zinc constitutes the anode.

Lohmannizing—In this process, iron and steel sheets are first immersed in a bath containing an amalgamating salt and then pickled and dipped in two different baths of molten alloys. The finished surface is in a clean condition and is coated with the protecting metal. The metals used in this process are alloys of zinc, lead, and tin, the proportions of which are varied to suit requirements. Terne plate is an example of this process.

Sherardizing—In the Sherardizing process the articles are placed in a revolving drum or retort with zinc dust. A small amount of powdered charcoal is added to prevent oxidation of the zinc. The retort is closed and heated to about 700°F. This process is used principally for bolts and small castings.

Metal Spray Coatings—The process consists of passing metal wire through a specially constructed spray gun which melts and atomizes the metal to be used as coating. The surface to be sprayed must be roughened, usually by sand blasting, to afford good adhesion of the deposited metal.

Chemical Coatings—The chemical coatings include Parkerizing and Bower-Barff Finish.

Parkerizing—This process consists of immersing the objects to be treated in a solution of manganese dihydrogen phosphate; then heating to about the boiling point. The pieces are allowed to remain in the bath until effervescence ceases. They are then removed and dipped in oil. The surface produced has the appearance of gun metal.

Bower-Barff Finish—This process consists of heating the objects to be coated in a closed retort to a temperature of 1600°F. Superheated steam is then injected, forming a coating of both magnetic oxide (Fe_3O_4) and red oxide (Fe_2O_3) of iron. Then carbon monoxide (CO) is injected which reduces the Fe_2O_3 to Fe_3O_4 . These operations could be repeated alternately any number of times until a sufficient depth of oxide has been obtained.

Greases—Greases and oils of various grades are used to protect the surface of iron and steel by applying a thin film over the surface. This method is especially useful for parts of machines, tools, and steels which are to be put in storage or are to be shipped. For details of this method see the article "Slushing Compounds".

Deactivation—Of late much has been said and written about the deactivation of water. In general, the method consists of passing the water to be used in a closed system over scrap iron to remove the dissolved oxygen. Once the oxygen has been removed, theoretically the water may go on circulating indefinitely in the system without corrosive action. Such installations have proved to be very successful.

Dissolved gas can be removed from water by passing the water over an electrically heated heat-resisting ribbon, allowing the gas liberated thereby to escape.

Iron may be made immune to corrosion by making it cathode, that is, by making it the negative pole in a cell, with a potential just sufficient to balance the solution pressure of the metal. This method is not used extensively because it is costly.

Mechanical Deaeration—Speller⁷ in his book has given a very complete summary of the principles involved and methods used in mechanical deaeration, and has said in part:

"Dissolved gases can be removed from water, if the temperature and pressure conditions are so regulated that the gases become insoluble, and if a sufficient

⁷F. N. Speller, *Corrosion, Causes and Prevention* 2nd. Ed., 1935.

amount of time is allowed for their complete mechanical separation from the water. The greater the surface area of a certain volume of water, or the greater the size of the gas bubbles, the smaller is the time required to separate the gases. Physical agitation of the water tends to coalesce the fine bubbles into larger ones, which separate from the liquid in a very much shorter period of time. Most types of mechanical deaerators function by agitating water when it is exposed to favorable temperature and pressure conditions. Removal of dissolved gases may also be facilitated by sweeping or agitating the water with a large excess of some other gas which is less objectionable or is harmless. Thus, following the laws of partial pressure, the gases in solution are carried away or greatly diluted. This principle is illustrated by the common practice of spraying water, high in carbon dioxide, over a mass of coke or other inert material exposed to the air. In this way the water is intimately mixed with air, and although the carbon dioxide by itself is very soluble, the amount in solution is reduced under these conditions to as little as 5 parts per million. Following this principle, in hot-water heating apparatus, the vapors arising from the water should be swept away by a current of air free steam. Otherwise, the freed gases may be re-absorbed by the water, and complete elimination will be impossible."

Many different types and designs of mechanical deaerators are daily performing useful and valuable service.

Corrosion Tests—There are several tests made on iron and steel to determine their deterioration due to corrosion. The tests usually made are salt spray, total immersion, alternate immersion, accelerated electrolytic, subjecting to atmospheric conditions, and subjecting to gases.

The test specimens are of various designs and often the finished object is subject to the test. The deteriorating effect of the immersion tests is determined by the loss in weight as well as the appearance of the surface. The size of the specimen and the condition of the surface should be alike if possible in order to obtain a satisfactory comparison.

The solutions used may be natural water, such as sea water, city water, or mine water, or special solutions may be prepared containing salts and acid. When preparing special solutions it is advisable to use distilled water, otherwise the impurities will enhance corrosion.

The interpretation of results in all tests should be based on the relationship of the results to practical service conditions. There are many factors which make it difficult to obtain quantitative results and before drawing conclusions the following should be considered: The temperature of the solution, the machined surface of the specimen before testing, the length of time subjected to the test, apparatus used, and the care exercised in cleaning and drying the specimen before weighing.

Summary—There are many things which are as yet unexplained, but certain facts are so well established that they may be wisely borne in mind, as follows:

Liquid water and oxygen are necessary for the corrosion of iron.

The rusting of iron may best be regarded as an electrochemical phenomenon.

The rate of corrosion of every piece of iron or steel depends on its composition, upon the means taken for its protection, and upon the individual conditions existing in the particular locality in which it is in use.

Critical Temperatures for S.A.E. Steels

By M. J. R. Morris,¹ G. W. Gable¹ and Robert Sergeson²

Introduction—It must be remembered that the position of the critical points is altered and will vary over a wide range the faster the heating and particularly the faster the cooling. Also, the critical points will vary with every constituent in

†The critical point determinations for these steels were obtained on a Leeds and Northrup transformation apparatus.

the steel. Therefore, the critical points given in the following tabulation may not always be consistent with the results obtained by others and should not be taken as absolute values for the critical points of the particular classes of steel listed.

The critical point determinations were made in a small laboratory electric furnace with automatic temperature control. The furnace samples were 1 in. round and $\frac{1}{2}$ in. thick and quenched in increments of 20°F. throughout the range on heating and cooling. The cooling rate was approximately the same as would be obtained in an uninterrupted furnace cooled annealing operation. Since the grain size and the exact rate of heating and cooling are not known, the results may be considered only as approximate.

Iron Alloys Containing From 3-20% Aluminum

By Dr. Kent R. Van Horn*

Aluminum is added to certain ferrous alloys in appreciable quantities to improve the electrical and magnetic properties or oxidation resistance of iron. The aluminum additions for these purposes range from 3-20% aluminum, and exceed the quantities used for nitriding steels or irons and for deoxidation. The commercial development of the alloys has occurred in recent years. The alloys may be classed according to two general types of applications, (1) electrical, and (2) heat resistance.

Electrical Iron Alloys Containing Aluminum—The improvement of the magnetic properties of iron or steel by aluminum is generally recognized. However, the beneficial influence of aluminum on magnetic permeability, like silicon, is indirect, namely, by its effect on carbon, oxygen and perhaps other elements, although directly aluminum would probably adversely affect pure iron. A 3½% annealed aluminum-iron alloy, vacuum melted, has a maximum permeability of 6 times, and a hysteresis loss of one-half of that of the commercial 3½% silicon transformer iron annealed in a similar condition.¹ The specific electrical resistance of iron is increased by 12 microns for each per cent of aluminum up to 3%. The electrical resistance of the 3½% aluminum composition is not so high as that of the 3-4½% silicon type. However, with the same method of preparation (vacuum melting) the silicon alloys are characterized by brittleness while the 3½% aluminum-iron has considerable ductility. There are some electrical installations where the aluminum-iron alloy has replaced the less expensive silicon types because the comparative brittleness of the latter was undesirable.

In 1934 patents were granted describing alloys containing aluminum for permanent magnets. An iron alloy containing 10-20% aluminum, 20% nickel, 5% cobalt, and no carbon, has qualities surpassing those of the 30% cobalt-tungsten permanent magnet type.² The exceptional properties of this material suggests an expanding field of magnetic applications.

Alloys Containing Aluminum for Electrical Resistors—A class of electrical resistors containing iron, chromium, and aluminum is marketed in this country as "Alcress" and "Ohmax",³ and as "Megapyr" in Germany. An alloy containing about 20% chromium, 5% aluminum, and the remainder iron, has a specific resistivity of 800 ohms per circular mil ft. If the aluminum content is increased to 10%, the material has a specific resistivity of 1000 ohms per circular mil ft. which is a higher value than that of the well known nickel-chromium resistors (650 ohms). The alloys containing aluminum also have an excellent resistance to oxidation at elevated temperatures. These two qualities and a lower density than the nickel-chromium type are utilized for applications where large resistance capacities are required for a minimum space, as in radio resistors. The alloys are more difficult to fabricate because of the presence of aluminum, but can be obtained for radio wires as small as 1 mil.

Another series of iron-chromium-aluminum resistors of similar composition and properties, but in addition contain some cobalt, is used in Europe and America for furnaces and electrical heating units demanding high temperatures or very compact units. This series of alloys called the "Kanthal" group consists of about 25% chromium, 5% aluminum, 3% cobalt, and the balance almost pure iron. The electrical resistance of the "Kanthal" series ranges from 812-872 ohms per circular mil ft. which is considerably higher than that of the 80% nickel, 20% chromium type (650 ohms). The density is lower than that of the nickel-chromium resistors, 7.15 as compared to 8.35 g. per cc. Ribbons or wires of the same sizes supplied in nickel-chromium can be fabricated and because of the superior resistance to oxidation are recommended for use at temperatures from 2000-2450°F. However, the tensile strength is low at elevated temperatures and it is necessary to provide suitable supports for elements in the installation.

A third iron base alloy⁴ of this type containing chromium, aluminum and small additions of other metals, for high temperature electrical resistors is known as "Smith Alloy No. 10". The chromium and aluminum contents are appreciably higher than in the two groups previously described, namely 37.5% chromium, 7.5% aluminum, and the balance iron. The alloy has the characteristics of the iron-

*Aluminum Research Laboratories, Aluminum Co. of America, Cleveland.

chromium-aluminum type of high electrical resistance, excellent resistance to oxidation and can be hot formed into the required bends and helices. The electrical resistance is 1000 ohms per circular mil ft. and the density of the material is 6.9, so that the volume is 22% greater than the volume of the same weight of the nickel-chromium type. It is, of course, necessary to provide the correct type of refractories (nonsilica) and suitable supports which allow for the thermal expansion, growth and the sagging of the elements. The three iron-chromium-aluminum types are effective for high temperature applications such as forge furnaces, heat treatment of high speed steel, and burning of ceramic materials. These resistors also compete with the nonmetallic silicon carbide type in the higher part of the recommended temperature range.

Aluminum Heat Resisting Irons—The outstanding resistance of iron-aluminum alloys to the action of heat was reported in 1931 by Hauttmann.⁷ The oxidation resistance of the binary aluminum-iron alloys increases with aluminum content from 4-9% aluminum. Ziegler,⁸ in 1932, found that 4% aluminum when added to iron (vacuum melting) produced a forgeable alloy with good oxidation resistance properties. Alloys of 6% aluminum have a slightly inferior and 8% aluminum, superior resistance to heat compared to the 80% nickel, 20% chromium type. These aluminum-iron alloys appear to be forgeable and the presence of carbon has little effect on the resistance to scaling. The significance of these pertinent technical discoveries has been evidenced by the inception of a number of irons to which aluminum has been added to impart resistance to oxidation.

The American Iron and Steel Institute has formulated specifications of a standard heat resisting type, 406-D, containing 12-14% chromium, 4.5% aluminum, 0.12% carbon, balance iron. Castings and forgings are produced, to a limited extent, by several companies.

Alloys containing 7-15% chromium, 2-6% aluminum, and 1% carbon, are forgeable if the total aluminum and silicon content does not exceed about 5.5% with the silicon⁹ about 1%. The steels may exhibit complete oxidation resistance at 1550-1850°F. depending on the total quantity of aluminum, chromium, and silicon. These alloys are used commercially, but have no wide application because the beneficial properties can be procured more economically with silicon. However, in the future the cost of the aluminum steels may be reduced by improved melting practice.

Aluminum has been added to the 18% chromium, 8% nickel stainless steel in quantities up to 3%, to prevent high temperature scaling and increase machinability without impairing the properties.^{10, 11} Modified casting alloys of this type containing aluminum are used for heat resisting applications and have trade names of "Fahr-alloy" and "Hybnickel" with certain designating numbers.

High silicon, high aluminum cast irons are one of the four types of "refractory" cast irons widely used in Europe for heat resisting applications. These alloys containing 6-9% silicon, 3-7% aluminum have good refractory properties, high resistance to oxidation but are not employed where high tensile values are required. The silicon-aluminum cast irons are considerably cheaper than the other three common types of European "refractory" irons.

High Yield Strength, Low Alloy Steels

By H. W. Gillett*

New types of low alloy steels have come on the market in the last few years to meet a demand for relatively cheap structural material with ductility and formability about the same as in ordinary structural steel, but with a decidedly higher yield point, and this without the necessity for heat treatment. To these requirements are added, for many purposes, those of weldability and resistance against atmospheric corrosion.

These steels are designed primarily for use where weight reductions are needed, especially in the transportation industries where lower dead weight without reduction in the strength of the members, opens the way to greater pay load. Cases where design is on the basis of static yield strength in tension can utilize smaller cross sections of high yield strength, but since the modulus of elasticity remains the same as in ordinary structural steel, stiffness has to be obtained by alterations in design to compensate for the smaller section and produce the necessary section modulus.

The necessary properties can readily be obtained from quenched and tempered carbon steels in small sections, but the large plates and shapes used in the structures for which these special steels are needed are unwieldy to heat treat and on account of the low depth hardening of carbon steels massive pieces would not be strengthened all the way through. Moreover, the strength obtained by heat treatment would be lost in the area affected by temperature, in welding, or flame cutting. It is therefore necessary that the required strength be obtained in the as-rolled condition.

Ordinary structural carbon steel of 0.20 carbon, 0.15 silicon, 0.50 manganese has a tensile strength of 50,000-65,000 psi. and a yield point of 25,000-30,000 psi. with an elongation in 8 in. of about 25-30%.

By raising the carbon to 0.40-0.45% the yield and tensile can be raised to 45,000 and 85,000 psi., the elongation dropping to 10-15%, while the notched impact resistance is at least halved. Decreased formability and the loss of ductility on cold working as in bending and flanging as well as air hardening and embrittlement in welding prevent the acceptance of such a steel.

By dropping the carbon and introducing alloying elements, the yield and tensile strengths may be increased without proportionately injuring ductility. Thus a steel of 0.15 carbon, 0.15 silicon, 0.30 manganese, 3.0 nickel may have a yield point of 40,000 and a tensile strength of 75,000 psi. with upwards of 20% elongation in 8 in. and up to about double the notched impact of ordinary low carbon structural steel.

Yield strength of this order was demanded in the early types of high yield strength steels, in cheaper ways than by the addition of 3% nickel. The carbon was cut to around 0.25-0.35% and the manganese increased to a higher figure, ranging from 0.75-1.75% with the lower manganese in the steels at the high end of the carbon range. The silicon was usually increased to around 0.30% hence these steels became known as "silicon structural steels," a misnomer since the increased strength was primarily due to the increase in manganese.

Less frequently the silicon was raised to 0.75-1.25% and the manganese held at 0.60-0.90%. The steels of 0.25-0.35% carbon with manganese and silicon as strengthening elements gave yield strengths of 45,000-65,000 psi. and tensile strengths of 80,000-95,000 psi. with elongations of about 16-22% in 8 in. In the lower carbon steels the notched impact resistance was held at about the level of ordinary structural steel.

These steels found use in bridges and similar structures, and in ship-building, and were acceptable for riveted structures. They are still used for such purposes, but are welded with some difficulty and their ductility is rather low for satisfactory cold forming.

Steels were then required with 50,000-60,000 psi. yield point with preferably not too high tensile strength, that is, a high yield ratio, and for a minimum of 22% elongation in 8 in., to insure satisfactory formability. Weldability was more insistently demanded, and since the thickness of plates was to be reduced in order to utilize the higher yield strength, improved resistance to atmospheric corrosion was called for so that the thinner plates would not pit through any quicker than the normal thickness of ordinary carbon steel.

*Chief Technical Advisor, Battelle Memorial Institute, Columbus, Ohio.

These requirements made necessary the adoption of lower carbon contents and the introduction of small amounts of alloying elements to make up for the reduction of the carbon, so manganese and silicon, chromium, copper, nickel, molybdenum and vanadium began to be utilized for their strength-giving effect.

Meanwhile the atmospheric exposure tests of the A.S.T.M. had shown that "copper-bearing steel," structural steel with around 0.20% copper, was improved in corrosion resistance. These tests showed also that increase in phosphorus content of a copper-bearing steel further improved the corrosion resistance. This fact pointed out by Storey¹ in 1921, was slow in being acted upon, but after about 10 years it was put to use. Beside the effect of phosphorus upon corrosion resistance, the facts that it is a strengthening element even more potent than carbon and that, if the sum of C + P is held below 0.25% the increase in strength can be had without static brittleness and with little effect upon impact, began to be realized. Hence phosphorus was added to the list of alloying elements.

While the bulk of the effect upon corrosion resistance is obtained at about 0.20% copper, further increase in copper to around 1½% confers some added resistance, and though the increase in strength due to 0.20% copper is almost imperceptible, addition of 0.40% or more, especially in conjunction with other alloying elements, was found to be worth while from the point of view of strength.

Moreover, when 0.60% copper or upwards is present, the steels become amenable to precipitation hardening, as Kinnear² showed, and as is discussed in the article on page 554.

Prior to the introduction of the higher percentages of copper for strength, all the older high yield point steels, of the carbon-manganese-silicon type, had become commercially available with the addition of around 0.20% copper for corrosion resistance. The addition of more than around 0.40% copper was held back by the fact that these higher copper steels are subject to preferential oxidation in scaling and tend to separate a film of copper beneath the scale if heated above the melting point of copper (see the article on page 558). This molten copper film penetrates in intergranular fashion and tends toward edge cracking and the production of checking on the surface in hot working. Lorig³ and others showed that the introduction of around half as much nickel as the copper present avoids cracking and checking, so that the use of a minor proportion of nickel in the higher copper steels became common. Strict control of soaking pit and reheating temperatures and rolling below the melting point of copper may also be utilized, and steel with 1% copper has been handled without nickel additions.⁴

Nickel is known to confer a degree of atmospheric corrosion resistance, somewhat analogous to copper, so the presence of even small amounts of nickel might be expected somewhat to enhance corrosion resistance, and the presence of say 2% should be definitely noticeable.

Chromium in large amounts, 12% and up, is of course known to confer superior corrosion resistance, while even 5% confers a definite improvement. The presence of 0.50-1% chromium does not have much apparent effect on corrosion and amounts of this order seem to be introduced chiefly as a strength-giving addition. Some improvement might be expected from such an amount. The proper balance of alloying elements cannot be predicted by a mere summation of the effects of the separate alloying elements. The steels of this class are not especially resistant to submerged corrosion, and their resistance to atmospheric corrosion depends on the exposure conditions being such as to build up a type of rust film that slows down further attack. They start to rust as rapidly as plain carbon steel.⁵

The grain refining effect of small amounts of molybdenum (0.20%) or vanadium (0.10%) is well known, and these, as well as aluminum or titanium (0.75%) are widely utilized to increase the ductility and notched impact resistance of as-rolled or normalized steels of the class under discussion. In some cases molybdenum is used in sufficient amount to act as one of the strengthening agents.

Several producers of ferroalloys or alloying elements have developed compositions embodying their products, and most of the major steel companies have selected a particular type composition selected from among the alloying elements mentioned above. The steels so devised are usually complex. One producer has followed the suggestion long ago made by Clamer⁶ and replaced part of the nickel in a low carbon 3% nickel steel, making the composition 2% nickel and 1% copper, without calling upon other alloying elements. Others utilize from 3-6 strength-giving elements beside carbon.

Most makers produce at least two grades, one (or more) in the range of 0.15-0.25% carbon plus moderate amounts of the chosen alloying elements, for nonwelding

uses, and a welding grade of 0.07 to (with some exceptions) 0.15% carbon. Several use 0.10-0.15% phosphorus, in which case the carbon is held from 0.07-0.13%, averaging around 0.10%. The low carbon grades are satisfactorily free from embrittlement on welding. A total of 0.25% C + P is probably a reasonable maximum, when the possibility of segregation of phosphorus in large ingots is considered.

With suitable precautions as to preheating before welding and stress relief annealing after welding, steels somewhat above 0.15% carbon are used for welding, but unless these precautions can be applied, the American Welding Society¹⁸ places 0.15% carbon as the upper limit for producing satisfactory toughness in the affected zone near the weld.* It suggests that the maximum tensile strength should be held down to 80,000-85,000 psi.

These welding grade steels, despite their low carbon content, 0.15% as a maximum, in usual commercial thicknesses of plate, as-rolled, fall within the ranges; yield point of 50,000-70,000 psi., tensile strengths of 70,000-80,000 psi. and 22-30% elongation in 8 in., with notched impact values at least equal to 0.20% carbon structural steel. The yield ratio of several of these steels is extraordinarily high. A minimum yield strength of 50,000 psi. is usually guaranteed and 55,000-60,000 psi. delivered. One maker favors the lower yield strength on the basis of formability and holds the average yield strength of its product as rolled, at 50,000 psi.

Several of the phosphorus-containing steels show endurance limits in rotary bending of 45,000-50,000 psi., the endurance limit approaching the yield strength. The endurance ratios obtained, 70-75%, are extraordinarily high. Endurance ratios on the higher carbon steels whose strength is gained from high manganese, run around the usual 45-50%, that is, approximately half the tensile strength. Endurance data are lacking on most of the newer steels, and the relative propensities toward notch propagation, which have a bearing on actual performance in service under repeated stress as contrasted with a laboratory test on a specimen free from stress-raisers, have yet to be evaluated.

Without citing properties for all grades of all these steels on the market the following may be summarized from the data supplied to Cone,⁶ and slightly modified on the basis of later information.

Tables I and II do not represent specification limits nor manufacturers limits of composition. The compositions are taken as representative ones, and the corresponding properties shown, where these are available. Some makers prefer to state minimum rather than average properties, so the tables should not be taken as placing each steel in its exact relation to the others.

That the plate thickness upon which the tabulated data were determined was not always stated is another reason why these figures should not be used for too fine intercomparisons. Further details can be had in the trade literature of the producing companies and in articles.⁶⁻¹⁴

The data do show the improved ductility of the low carbon group compared with the high carbon group, also that in the former class the desired yield strength may be attained with a wide variety of alloying elements. Other combinations than those listed could be employed, and there is no finality or standardization as to composition in sight.

Foreign steels of this type have also been developed. A copper-chromium steel commercially produced in England was stated in 1934 to contain 0.22-0.26 carbon with about 0.10 silicon, 0.80 manganese, 0.30 copper and 0.90% chromium. More recently Britton¹⁶ indicated that both the carbon and chromium had been dropped, citing a composition of 0.15 carbon, 0.07 silicon, 0.65 manganese, 0.31 copper, 0.65% chromium, which in sheet 0.035 in. thick showed 67,000 psi. tensile, 49,500 psi. yield point, 13% elongation in 8 in. In discussion of Britton's article, Portevin gave the following analyses for French steel of this type:

C	Si	Mn	Cu	Cr
0.15	0.17	0.70	0.57	0.48
0.08	0.94	0.32	0.42	0.80

According to Zeyen¹⁷ the German railway specifications for "Stahl 52," call for limiting the composition to the following maxima 0.20 carbon, 0.50 silicon, 1.20 manganese, 0.55 copper, 0.06 phosphorus, 0.06 sulphur (P + S 0.10), to which may be added either 0.30 manganese (making the Mn 1.50), or 0.40 chromium or 0.20 molybdenum.

*Not all producers agree with this, feeling that, if the rest of the composition is suitable, 0.18 or perhaps even 0.20% may be permitted.

^aWhen specified.

Steels 8 and 9 are given their strength by low finishing temperature, below the critical. The other steels could be made stronger and less ductile by similar procedure. Steel 8, of weldable composition is not listed in Table I since strength conferred by cold work will not be expected to be retained in applications heated in welding. Steel 8 has not been included in Table I for this reason though the makers state that the strength of welds is practically that of the plate. Hot forming up to 1500° F. is said not to affect the properties. The endurance limit of No. 8 is given as 45,000 psi.

^aWhen specified.

Steels 8 and 9 are given their strength by low finishing temperature, below the critical. The other steels could be made stronger and less ductile by similar procedure. Steel 8, of weldable composition is not listed in Table I since strength conferred by cold work will not be expected to be retained in locations heated in welding. Steel 8 has not been included in Table I for this reason though the makers state that the strength of welds is practically that of the plate. Hot forming up to 1500°F. is said not to affect the properties. The endurance limit of No. 8 is given as 45,000 psi.

Zeyen gives the following for plate 0.47 in. thick, as representative of German practice:

	C	Si	Mn	P	S	Cu	Cr	Mo	Tensile Strength, psi.	Yield Point, psi.	Elong., %	Impact, mkg./cm. ²
Krupp	0.18	0.50	1.43	0.026	0.017	0.48	86,000	55,500	25	10.5
Union	0.17	0.45	0.87	0.037	0.017	0.49	0.17	...	74,000	50,000	20	12.5
Gutehoffnungshütte	0.15	0.52	0.98	0.031	0.024	0.25	0.02	0.11	74,000	47,000	21	13

From the known costs of the alloying elements used it is obvious that some of the compositions listed are more expensive than others. But ability to be rolled into difficult shapes, uniformity of properties in sections of varying sizes and other manufacturing matters affect the cost of the finished steel.

From the users' point of view the weldability and the properties of the welds, the ability to be cold formed, and the actual corrosion resistance in service are features upon which the final choice will depend. Without doubt the steels differ somewhat in these properties, but evidence for full evaluation will take years to accumulate.

Sufficient evidence as to usefulness is at hand so that the steels are coming into use, especially in the construction of light weight freight cars. Streetcars, trucks and busses utilize them to some extent. Their use in shipbuilding is beginning.^{11, 12}

Gibson¹³ has described their use in heavy welded construction, such as turbine runners, engine bases in submarine service, and especially in such things as drag line buckets. When large sections are available uses of this type will increase.

They seem to have little application to automobile or aircraft needs which are met by heat treated steels, but when the problem of increasing payload comes up in construction so heavy that quenching and tempering are not applicable, the low alloy steels deserve consideration.

Properties of Forgings in Heavy Sections

By A. W. Demmler* and Jerome Strauss†

As a prerequisite to the heat treatment of steel to meet definite physical properties, sound steel must first exist in the forging; this, of course calls for an initially sound ingot. While both acid and basic open hearths are applicable, the largest forging ingots ordinarily are of acid steel poured into corrugated big-end-up molds. Acid practice necessitates raw materials low in sulphur and phosphorus. A sound ingot is only possible with fully killed steel and to insure thorough deoxidation, the final deoxidation is commonly accomplished in the ladle when large ingots are involved. The nature of this deoxidation or final control practice is of special concern especially when transverse properties are paramount for the application. Here a minimum of banding is desirable aside from any regulation of grain size.

Large ingots may stand (in the mold) for days to insure complete solidification before being transferred to the forge furnace, and further, a large hot top is necessary to supply the shrinkage in the body of the ingot as the metal freezes. Large ingots should be transferred to a heating or equalizing furnace while there is still color in the body; this is vital to avoid severe stresses in a coarsely crystalline mass which would otherwise have a distinct temperature gradient from surface to center that might involve transformation changes, plastic deformation in certain zones and internal ruptures. Large masses in the as-cast state do not possess ductility to a marked degree. It is advisable first to allow the ingot to equalize from center to surface with the furnace in the range of 1200-1500°F. before attempting to raise the temperature. The heating to forging temperatures (approximately 2200°F.) should not be rapid as a serious temperature gradient is undesirable. Where appreciable alloy content is present the rate of heating should be somewhat slower than one hour per inch of thickness. Nonuniform heating or impingement of the heating flame may also result in serious damage to the ingot. No forging work should be attempted until the heat has thoroughly soaked into the heart of the section.

The initial working should consist of slight reductions on all sides to consolidate the metal. After the steel has received this light working, greater reductions can be safely made. For penetration of the working to the center of large masses a press is necessary. With full penetration during the forging operation it may be possible to weld clean ruptures which may have originated in the solidification of the ingot or in its initial heating. Full penetration of the hot working is also necessary to break down the coarse crystallization of the steel throughout the heavy section. The finishing temperature in forging should be low enough to avoid excessive grain growth in the steel after it is laid down; at the same time it must not be so low as to result in forging ruptures in those alloy steels that have high strength at elevated temperatures. Common practice is at least 3:1 reduction in cross section from the ingot while 2:1 reduction is not uncommon where transverse tests are specified; of course, upsetting (which may be in several stages) or expanding is beneficial to transverse properties also.

Caution is advisable in cooling the finished forging and also any balance of the ingot or bloom which may remain. Simple low carbon steels may usually be cooled in still air, but higher carbon or alloy steels should be immediately annealed or cooled in ashes; otherwise, internal ruptures may develop. Annealing may be absolutely necessary to permit ready machining of some compositions. Reference is suggested to Handbook articles for Large Forgings and the Heating, Forging, Annealing, and Normalizing of Locomotive Forgings.

Where design permits, it is best to bore heavy forgings. The boring is beneficial from practically all viewpoints: Unsound metal may be removed, segregation may be eliminated, inspection is simplified, and heat treatment is simplified and rendered more effective.

The more common heat treatments for large forgings are either annealing or normalizing or possibly both; a tempering treatment 1050-1250°F. is advisable following normalizing while the cooling from this lower temperature may be in the furnace or in still air. Although the greatest ultimate grain refinement will result from a treatment temperature not greatly above the critical, an initial higher temperature normalizing or annealing is generally necessary to develop homogeneity of structure. In a large forging, especially if finished hot on the press, a single homogenizing and

*Metallurgical Engineer and †Vice President, Vanadium Corp. of America, Bridgeville, Pa.

a single refining treatment will probably not accomplish satisfactory refinement; several stages of refining are usually necessary.

Where conditions will permit, liquid quenching, spray quenching, or cooling in an air blast will result in higher strength properties; of course, a tempering treatment is necessary. Reasonable uniformity of section throughout the forging is vital for this more drastic quenching, and sharp fillets must be avoided.

A number of different steel compositions have been used for heavy forgings and the properties obtainable for different types of heat treatment are presented in the following tables. The air quench treatments are single treatments while for the most part, the liquid quenched forgings have been initially normalized. These forgings are applied to such parts as crusher shafts, rams, rotor shafts, ship propeller shafts, rolling mill shafts, sugar mill shafts, or axles.

Melting and forging details have been available in only a few cases, so that none of these features has been included. However, the nature of the refining, final deoxidation and grain size regulation enter into the ultimate properties, more particularly as mentioned earlier, when transverse properties are involved.

Magnetically Soft Materials

By T. D. Yensen*

Introduction—Several conflicting characteristics are often required in magnetically soft materials. For this reason a number of different magnetic alloys ranging from pure iron through the silicon irons to the high nickel-iron alloys have been developed. The characteristics of importance are: (1) Hysteresis loss on passing through a magnetic cycle and arising from internal magnetic "friction." This should be low. (2) Eddy current loss due to electric currents induced in the material by changes in flux. This should be low. (3) Magnetic permeability should be high and sometimes must be high or constant at low field strengths. (4) Saturation value should be as high as other considerations permit. (5) In special applications a definite change in permeability with temperature is required. (6) The cost, availability and ease of processing are important.

Effect of Impurities—As the ferromagnetic properties are a function of the regularity of the space lattice, it follows that anything that affects this regularity will also affect the magnetic properties. Impurities like carbon, sulphur, nitrogen, and oxygen are particularly harmful, because when in solution they occupy interstitial spaces in the crystal lattice and very small amounts therefore produce large effects.¹ Furthermore, as the solubility is low at room temperature, the

Fig. 1—Net effect of grain size on hysteresis loss of pure iron.

Fig. 2a—Effect of carbon on the hysteresis loss of iron.

Fig. 2—Effect of grain orientation on the B-H properties of iron (Honda and Kaya).

excess amount is slowly precipitated in the form of small particles inside the grains with even greater disturbing effect, usually referred to as "aging." Carbon especially should be kept low in iron and iron-silicon alloys in order to obtain low hysteresis loss and high maximum permeability. The amount should not be over 0.01% and

*Manager, Magnetic Div., Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa.

preferably less than 0.005%. Fig. 2a shows the effect of carbon on the hysteresis loss of iron. Sulphur and oxygen should likewise be held down to similar values.

Effect of Grain Size—Because of the disturbances at the grain boundaries, the fewer the grain boundaries the better are the magnetic properties, which is another way of saying that the grain size should be as large as possible with the single crystal as the limit, Fig. 1.

Effect of Grain Orientation—Almost all ferromagnetic materials are magnetically anisotropic, that is they have different magnetic properties in the different crystallographic orientations. This is shown in Fig. 2 for iron² and in Fig. 3 for an iron-silicon alloy with 3.85% Si.³ In both of these cases the direction parallel to a cube edge [100] is the one having the highest permeability. In other cases this is not so, for example, in Ni the situation is just the reverse: The direction of easy magnetization is that of the body diagonal [111]. So in all cases crystal orientation should be taken into account in controlling the magnetic properties of ferromagnetic materials.

Effect of Alloying Elements—While pure iron may in many respects be regarded as the ideal ferromagnetic material, it has certain drawbacks that makes it unsuitable for practical use especially in a.c. circuits. The resistivity is low, necessitating rolling the iron very thin to keep eddy currents down, and when this is done, the magnetic properties are poor. One of the main objects

Fig. 3—The observed and calculated magnetization curves for the [100], [110] and [111] directions of single crystals of 3.85% silicon iron (Williams).

Fig. 4—Effect of elements on the electrical resistance of iron (Stablein and Yensen).

of alloying elements is therefore to raise the electrical resistivity of iron so as to enable us to use it to advantage in a.c. circuits (which means perhaps 75% of all applications of magnetic materials in industry). Fig. 4 shows how the various elements affect the resistivity of iron. Outside of carbon in solution, silicon and aluminum increase the resistivity more than any other element.

These two elements also have another important effect: They eliminate the allotropic transformations in iron, so that the alloys can be annealed at high temperatures without recrystallization on cooling, thus permitting large grains. Both these elements are substitution elements and for this reason can be added to iron in fairly

large quantities without affecting seriously the magnetic properties, although they do reduce the saturation value. However, more than 4.5% silicon or 8% aluminum makes iron too brittle for most commercial use.

Another reason for keeping the alloying elements down to low values is that all elements, with the exception of cobalt, lower the saturation value of iron, Fig. 5.

The chief difficulty in connection with silicon and aluminum is that they form stable oxides, so that if the iron is not thoroughly deoxidized before adding the alloying elements, oxide inclusions are formed that cannot again be eliminated and have deleterious effects on the magnetic properties. Aluminum is particularly bad in this respect.

Unsuspected and valuable magnetic properties are obtained by combining iron with nickel or with nickel and cobalt and by adding to these combinations other elements like copper, molybdenum, or chromium, as will be seen later.

Magnetic Materials—Iron—

By careful preparation of a single crystal of iron Cleffi has obtained a maximum permeability of 1,430,000 and Ziegler and Yensen² have prepared ring samples of iron having a hysteresis loss of 70 ergs per cc. per cycle for $B = 10,000$.

For experimental uses iron can now be obtained with a purity of 99.95% or better, having magnetic properties as shown in Fig. 6: Maximum permeability of about 100,000 and a hysteresis loss for $B = 10,000$ of about 100 ergs per cubic cm. per cycle (Wemco iron).

The latest saturation value of iron comes from the Physikalisch-Technische Reichsanstalt³ and is given as:

$$4\pi I_s = 21,580 \pm 10 \text{ gauss}$$

based on a density of 7.878.

These values agree well with those given by Cleaves and Thompson.¹ The electrical resistivity given by Cleaves and Thompson as the most reliable value is 9.8 microhms per cubic cm. at 20°C. with a temperature coefficient of 0.0065 per °C.

Iron-Silicon Alloys—Although pure iron may in many respects be regarded as the ideal magnetic material, it is easier to obtain good magnetic properties in iron by the use of a small amount of silicon than without it.^{11, 12} Brittleness imparted by the silicon limits the amount in practice to about 4.5%, although 6% may be used for special purposes.

See the article in this Handbook for further information on iron-silicon alloys.

Fe-Al and Fe-Al-Si Alloys—

While aluminum is known to have about the same effect on iron as silicon, both as to electrical resistivity

Fig. 5—Effect of elements on the saturation values of iron (Stablein and Yensen).

Fig. 6—(Upper) Hysteresis loops and B-H curves for nearly pure iron. (Lower) Hysteresis loop of Hipernik in comparison with silicon iron.

and magnetic properties,⁹ it has never become a serious competitor on account of the difficulties in connection with the manufacturing processes. Ternary alloys of iron, silicon and aluminum have recently been investigated by Masumoto.¹⁰ The alloy contained 8-11% silicon and 5-6.5% aluminum and is reported to have an initial permeability up to 35,000, a maximum permeability up to 162,000 and a hysteresis loss down to 28 ergs for $B = 5,000$. With such high silicon and aluminum contents the saturation value is necessarily low ($4\pi I_s = 11,000$). The alloys are brittle.

Fig. 7—Saturation intensity of iron-nickel alloys. Electrolytic iron and nickel, melted and annealed in vacuum. From 0.5-1% Mn added to alloys with more than 30% nickel to facilitate forging.

nickel that had unusually good magnetic properties. At still lower magnetizing forces, the optimum composition has been found to be in the region of 70-85% nickel.

While these alloys are basically iron-nickel alloys, appreciable percentages of other elements are added in many cases to develop or accentuate some particular characteristic which is desirable for the application in view.

The trade names,¹¹ approximate composition and applications of the most important iron-nickel alloys are given in Table I.

Annealed iron-nickel alloys containing between 30-90% nickel have initial permeabilities higher than that of Armco iron. Alloys containing more than 50% nickel are sensitive to heat treatment as shown in Fig. 8. The heat treatment that improves initial and maximum permeability consists in air quenching thin strips on a copper block from the magnetic transformation point. The most startling results were obtained for alloys in the neighborhood of 80% nickel (the best composition being 78½%), and the name "Permalloy" was given to the alloys in this range. Maximum permeabilities of 100,000 are readily obtained with this alloy (Fig. 9) but the saturation value is low (11,000) and its electrical resistivity is only about double that of iron. However, it was later found that the resistivity could be markedly increased by the addition of chromium or molybdenum, which at the same time eliminates the necessity for air quenching and increases the initial permeability to over 20,000, but at a further sacrifice of saturation value.¹² Table II gives the principal characteristics of the important alloys in this group, together with Armco iron and other alloys.

Fig. 8—Initial permeabilities of the iron-nickel series (Elmen).

⁹In the preparation of this section liberal use has been made of Data Sheet No. 2, "Iron-Nickel Alloys for Magnetic Purposes," prepared by J. W. Sands, of The International Nickel Co., Inc., for their Iron Nickel Data Book (1938).

T. D. Yensen: Franklin Inst. Centenary Celebration, Sept. 19, 1924. J. Franklin Inst., 1925, v. 199, p. 323.

70-7.5 Perminvar, annealed	750	3,5008	12,000	16

^aSingle numbers preceding the word "Permalloy" signify the nickel content, and double numbers signify first the content of chromium or molybdenum, and second the nickel content, the balance being iron in each case. The two large numbers before "Perminvar" indicate the nickel and cobalt contents, respectively, and the small initial number indicates the molybdenum content.

^bFor saturation value of the flux density.

^cSaturation value of the intrinsic induction.

50% Nickel-Iron Alloys—The alloys in the region of 50% nickel exhibit nothing remarkable (Fig. 7) except that their saturation values are the highest of all iron-nickel alloys above 30% nickel. By ordinary pot annealing a maximum permeability of 20,000-25,000 can be obtained with an initial permeability of 2,700, if pure material is used. Such an alloy is 45% nickel listed in Table II, the permeability curve of which is shown in Fig. 9.

The magnetic properties of these alloys can be vastly improved by annealing them in dry hydrogen at a temperature of 1000-1200°C. for several hours.¹³ This treatment reduces carbon, sulphur and other impurities, but particularly oxygen. In its improved form this alloy has been given the name "Hipernik" (from high permeability nickel). The nickel content is not particularly critical, it may be varied from 40-60%, but for highest saturation value it should be kept close to 50%, see Fig. 6.

The use of this alloy in place of ordinary 4% silicon iron for transformer cores would result in a reduction of energy losses to about one-half. However, because of its high cost, its use is limited to special transformers, such as current transformers in which, because of its high permeability and low loss, the ratio errors and phase angle deviations are reduced to negligible quantities. Cold rolled in the form of continuous ribbon, this alloy is particularly suitable for bushing type of current transformers, as in this way there is no waste of material.

While this 50% Ni alloy cannot compete with the higher nickel alloys for applications requiring the highest initial permeability, it is preferable for most other uses, because of its higher saturation value (Fig. 7).

In Table III are listed the magnetic properties of this alloy in comparison with values of other alloys.

Fig. 9—Permeability curves for various magnetic alloys (Wise).

Miscellaneous—Numerous modifications have been made in these alloys by the addition of other elements and by variation in the heat treatments. They are made by various companies here and abroad, the most important of which are listed in Table IV.*

By cooling some of these alloys in a magnetic field through the magnetic transformation point, great improvements have been obtained.¹⁴ Particularly good results were obtained with 65% Ni and with 45% nickel, 30% iron, 25% cobalt. A maximum permeability of over 600,000 was reported for the 65% nickel alloy. The cause of the improvement is explained on the basis of elimination of strains due to magnetostriction.

*Prepared by J. W. Sands and T. D. Yensen from data obtained from Aciéries d'Imphy, Telegraph Construction and Maintenance Co.

Materials with High Magnetic Saturation Value—Iron has a saturation value of 21,600 ($4\pi I_s$). To exceed this value, it is necessary to alloy iron with cobalt in amounts between 0 and 65%. The highest value is obtained by using 34.5% cobalt.

^aSee Table I for chemical compositions.

^bConstant permeability of over 2,000 for $H < 0.06$.

The saturation value of 24,200 is regarded as well established (Fig. 5) for 34.5% cobalt-iron, corresponding to Fe_2Co .

A 50% cobalt alloy according to Elmen¹⁷ with the addition of a small amount of vanadium is easy to forge and roll and because of its better magnetic properties below $H = 200$, it is preferable to the 34.5% alloy where cost is of no importance. The name "Permendur" has been applied to this alloy.

Materials with Constant Permeability—At the Bell Laboratories were developed

certain iron-nickel-cobalt alloys¹⁸ having a constant permeability at low magnetizing forces. These, containing in the neighborhood of 30% iron, 45% nickel, and 25% cobalt were called "Perm-Invar." They are useful wherever a constant inductance or reactance is essential such as in filter coils for radio circuits or for loading coils for telephone circuits, where air gaps are otherwise used with sheet materials. Fig. 10 shows the hysteresis loops for the optimum composition. Similar (but not so good) results may be obtained with 50% iron-nickel alloys by means of a special heat treatment which, in fact, is an incomplete annealing below 800°C .¹⁹

A more recent development²⁰ in Germany resulted in iron-nickel alloys called "Iso-perms" containing 35-55% nickel. Aluminum, copper, beryllium, manganese, and titanium have been used with varying success. The best alloy contains 40-45% nickel, 45-50% iron, and 5-15% copper. The alloy is first drastically cold rolled, then quenched from a high temperature, further cold rolled, and finally annealed, a treatment by which the copper is precipitated in such a way as to produce a preferred arrangement of the iron-nickel lattice, resulting in low retentivity and constancy of permeability (50-60)

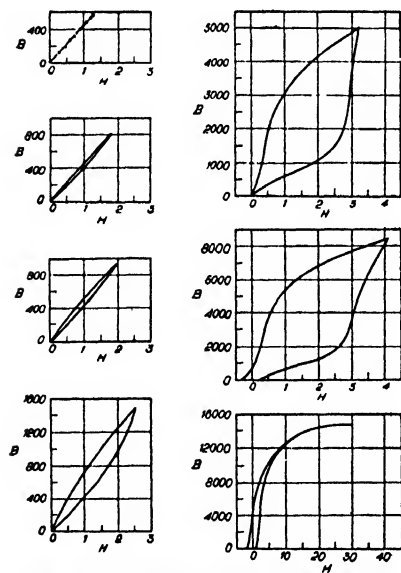

Fig. 10—Hysteresis loops for alloy containing 45% nickel, 25% cobalt, and 30% iron—annealed.

over a wide range of H (0-100 oersteds).

Alloys for Magnetic Temperature Compensation—Because of the fact that the magnetic permeability of iron and iron alloys decreases with temperature (except for low values of H) the reading of electrical meters that depends upon the flux produced by a constant voltage supply or by a certain load current, such for example as watt-hour meters, decreases with the ambient temperature. To compensate for

such errors it is customary to shunt a certain amount of the magnetic flux around the moving part of the meter by means of an alloy having an unusually high magnetic temperature coefficient between 0 and 100°C., so that, as the ambient temperature increases, the amount of the shunted flux decreases, forcing more of the flux through the moving member than otherwise would be the case. By proper proportioning of the parts, it is thus possible to compensate almost completely for the temperature changes. Alloys for such purposes are essentially of two types:

(1) The nickel-copper type having a composition around 70% nickel, 30% copper with certain admixtures, such as 2% iron (Calmalloy²¹); or with about 1% manganese with or without a small amount of silicon (Westinghouse Alloy²²).

Characteristic curves are shown for these alloys in Fig. 11.

(2) The nickel-iron type containing around 30-40% nickel with a small amount of Mn, Cr and Si. Curves for this type alloy are shown in Fig. 12. All values of H from low temperatures up to 60°C. are nearly straight lines and higher temperature coefficients than for the 70% nickel-30% copper type of alloy.

Permanent Magnet Alloys

By K. L. Scott*

Introduction—This article was written during a period of great development activity in the field of permanent magnet alloys. As a result of this activity, there are commercially available two distinct types of materials for making permanent magnets; namely, the older and well known types of magnet steel, and the new, precipitation hardening alloys. There is a possibility that compressed metallic oxide magnets may be added as a third type.

Theory of Permanent Magnets—In order to understand the relative importance and usefulness of each type of material, a brief resumé of the fundamental theory of permanent magnets will be given. In Fig. 1 is shown a typical hysteresis loop and magnetization curve for a permanent magnet alloy. The variables are

magnetizing force, H , in Gilberts per cm. ($\frac{4-\pi}{10}$ —times ampere turns per cm.) as

abscissae and magnetic flux density, B , in gauss (so-called "lines of force" per sq.cm.) as ordinates. Starting with an unmagnetized specimen, if increasing values of H are applied (as by gradually increasing the electric current in a coil of wire wound on the specimen) the corresponding values of magnetic flux produced in the specimen will be as shown by the normal induction curve. If now the values of H be gradually reduced from the highest applied value, H_{max} , to zero and then increased in the negative direction to a negative H_{max} (accomplished by reversing the current in the magnetizing winding), the value of B will change from a positive B_{max} to a negative B_{max} along the left-hand curve of the hysteresis loop. If this process be repeated, starting with a negative H_{max} , the right-hand side of the hysteresis loop will be traced. If the value of magnetizing force be reduced from H_{max} to zero (as by opening the circuit of the magnetizing winding) the value of B will drop from B_{max} to the intersection of the hysteresis loop with the B axis. The value of B at the point of intersection is called the residual induction, designated B_r . If there is now applied sufficient negative magnetizing force to reduce the value of B from B_r exactly to zero, the value of negative H required will be as shown by the intersection of the hysteresis loop with the

Fig. 1—Typical hysteresis loop of permanent magnet alloy.

H axis. This particular value of H is called the coercive force, designated H_c . The descending branch of the hysteresis loop between the points B_r and H_c is most important in permanent magnet theory. It is known as the demagnetization curve. If the product of the coordinates, B and H , of this curve are plotted against corresponding values of B , a new curve is obtained, as shown in Fig. 2. The maximum value of the product $B \times H$, designated $(BH)_{max}$, as obtained from this curve, is proportional to the maximum amount of magnetic energy which a magnet of the given material can support in an air gap, per unit volume of material in the magnet. Hence, the most efficient magnet design will be one which works the magnet at the flux density corresponding to the $(BH)_{max}$ point of the material.

It is not necessary to plot the curve of $B \times H$ against B to determine the value of $(BH)_{max}$, or the corresponding value of B . The coordinates of the $(BH)_{max}$ point are determined to a close approximation by the intersection of the diagonal of the rectangle having sides $(0 B_r)$ and $(0 H_c)$ with the demagnetization curve, as shown in Fig. 2.

Since the value of $(BH)_{max}$ is proportional to the maximum maintainable air gap energy per unit volume of a magnet, it constitutes a criterion of the magnetic quality of a permanent magnet material. It has been shown empirically that the quantity $(BH)_{max}$ is proportional to the product $B_r \times H_c$. Hence this product can also be used as a criterion of magnetic quality. It has also been shown that the

*Engineer, Western Electric Co., Chicago.

coordinates B and H of the $(BH)_{\max}$ point are equal, respectively, to approximately 0.65 B_r and 0.65 H_c . Hence the determination of B_r and H_c for a material serves to determine its magnetic quality as a permanent magnet material, and also to determine the flux density at which magnets of the given material should be designed to work.

It has been shown also that the flux density of a fully magnetized bar magnet, designated B_{rm} , depends upon the length L and equivalent diameter, D , in the manner shown in Fig. 3. This curve holds for all permanent magnet materials, but applies strictly only to straight bars. The curve will also apply quite well to magnets of other shapes, however, unless the ends of the magnets are quite close together, or are brought effectively close together by iron pole pieces. In most cases the curve can be used as a check on the measured flux values of formed or cast magnets of various shapes when magnetized and tested as bare magnets. In these cases the actual flux values obtained should never be lower than predicted by the curve.

Testing of Magnet Materials and Magnets—Most manufacturers and large users of permanent magnet steels or alloys test the materials for magnetic quality by measuring B_r and H_c . The tests are made in some form of permeameter on straight bars of cast or rolled material, after proper heat treatment. Methods and equipment for making these tests are described in A.S.T.M. Standard Method of Testing A-34-33.

Most magnet users also make a flux test on the finished magnets. This test can be made most accurately with a search coil and a flux meter of the galvanometer type. Sufficient accuracy for commercial purposes and greater speed are obtained with flux meters of the direct current meter type in which the test magnet furnishes the field to deflect the moving coil of the meter.

Aging of Magnet Materials and Magnets—The magnetic properties of the permanent magnet steels are not stable with time. The residual induction and coercive force of most magnet steels begin to change spontaneously as soon as the steels are hardened and continue to change for an indefinite time. The rate of change is greatest immediately after hardening, and decreases rapidly so that in a few days the rate is slow. The rate and amount of change differ for different kinds of steel and are not uniform for any given kind of steel. The direction of the change is always for the residual induction to increase and the coercive force to decrease. Because of this instability, it is good practice for a user of magnet steel buying under specifications of magnetic properties to allow an aging period to elapse between the hardening and testing of test bars.

Because of their nature, and the kind of heat treatment employed, such aging phenomena are known to be much less pronounced in the precipitation hardened alloys and may be absent in some of them. An increase of coercive force with time has been observed in test bars of iron-nickel-cobalt-aluminum with no change in residual induction.

The state of magnetization of magnetized magnets made of a magnet steel is also subject to a peculiar instability. It is observed that magnets magnetized immediately or soon after hardening will spontaneously suffer a decrease in flux beginning immediately after magnetizing. The rate of loss of flux is greatest immediately after magnetization, and decreases rapidly with time, so that after several days the flux has reached an approximately stable value. If the magnet is remagnetized, the same phenomenon is repeated on a smaller scale. The phenomenon, however, is only temporary and disappears with a sufficient lapse of time after hardening.

This phenomenon is not found in the commonly used precipitation hardening alloys and is probably of negligible importance in all of them.

The loss of flux that occurs in magnets due to external demagnetizing influences is also commonly but improperly referred to as aging. External demagnetiz-

Fig. 2—Typical demagnetization curve of permanent magnet alloy.

ing influences include mechanical shock, adverse magnetic fields (this includes alternating current fields and the fields of other magnets) and heat. In general, if a magnet is weakened by any one of the above means, it will not be further weakened by a repetition of the same treatment and will suffer only a slight loss in flux from the application of any other treatment that would have weakened it originally by about the same amount. In the process inspection of magnets after hardening, some users follow the magnetizing operation by a partial demagnetization or "aging", before testing. The partial demagnetization in the inspection process is for the purpose of eliminating magnets that are improperly hardened or made of defective material and is not intended as a stabilizing treatment. If a stabilizing treatment is required, as for magnets to be used in measuring instruments, they may be stored for a long period of time, subjected to heat as by immersion in boiling water, or merely be partially demagnetized by an a.c. or d.c. field after final magnetization.

Methods of Magnetizing Magnets—The problem of magnetizing permanent magnets is becoming increasingly difficult with the advent of materials with coercive forces above 200 oersteds. The magnetizing field required fully to magnetize a magnet is several times the coercive force of the material, amounting in some cases to as much as 1500 ampere turns per centimeter. The magnets made of low coercive force steels and most magnets made of cobalt steel can be fully magnetized by means of large electromagnets. Precipitation hardened magnets of favorable shapes can also be magnetized by the same means, but magnets of intricate shapes made of cobalt steel or the precipitation hardening alloys can only be fully magnetized by winding heavy wire on each magnet and sending a heavy current through the wire by shorting the winding across a suitable source of heavy current. In this case, it is advisable to protect the current source and the winding by using a fuse in series. The fuse wire will melt and open the circuit before damage occurs to the current source or the magnet winding.

Magnet Steels—The types of magnet steel produced commercially in the United States are classified by their manufacturers as follows: Carbon-manganese, chromium, chromium-molybdenum, tungsten, and various grades of cobalt steel including cobalt-chromium and cobalt-tungsten. The chromium steels are made in grades ranging from nominal 1% chromium to 6% chromium, the tungsten steel ranges from 5-6% tungsten, and the cobalt steels contain from 3-36% cobalt with chromium from 2-10% and tungsten from 1-10%, and a fraction of 1% molybdenum in some cases. In some instances, the tungsten steels contain sufficient chromium to make them oil hardening. Otherwise, the tungsten steels, the 2% chromium steel, and the carbon manganese steels are water hardening and all the rest are oil hardening. It is noteworthy that the 1% chromium steel has the best magnetic properties when quenched in oil; but that water, some water solution, or a light oil are universally recommended for the 2% chromium steel. Data concerning the various types of magnet steel are shown in Table I. Only those types reported by various American manufacturers are included, and the data are summarized from information furnished by the manufacturers.

Manufacture of Magnet Steel—In general, the methods of melting, rolling, and fabricating magnet steels are similar to those used for tool steels of similar composition. Exceptions arise from the fact that mechanical properties are of secondary importance and practices which would be harmful to the magnetic properties must be avoided as much as possible. In particular, this means that the thermal history of the steel should be as brief as can be. Rolling or forging should be accomplished with a minimum amount of reheating and overheating should be avoided. Annealing should not be resorted to unless necessary for machining operations and the anneal should be as light as is consistent with machinability. Forming temperatures should be just high enough for proper working of the steel. It is rarely feasible to restore the magnetic properties of magnet steel which have been damaged by too prolonged heating or overheating.

Fig. 3—Relation between magnetic properties and dimensions of straight bar magnets.

Melting and Rolling—Magnet steels are quite universally melted in electric furnaces, either arc or induction. One exception lies in the use of open hearth furnaces for melting carbon-manganese steel and the chromium steels of lower chromium content where larger tonnages are involved. In some cases ingots are cooled in lime, dry sand, or other material before rolling; but where possible it is preferable to break them down without cooling. This is done either by forging or rolling. Surface defects are generally removed by grinding. The rolling temperatures at start range from 1800-2100°F. and the finishing temperatures from 1300-1700°F., depending upon the critical temperature of the steel.

Hot Forming—In most cases, the shapes of permanent magnets are such as to require hot forming. This may be done satisfactorily at temperatures between 1400°F. and 1800°F. Higher temperatures are detrimental to the quality of the steel. A medium temperature is preferable and the heating and forming should be done as quickly as possible. Magnets are generally air cooled after forming. In some cases, magnets are hardened by quenching immediately following the forming operation, thus eliminating one heating operation. This practice requires better than ordinary control of the forming temperature.

Annealing—Too much emphasis cannot be laid upon the desirability of designing magnets so that they do not require annealing for machining operations. Where this is unavoidable, as light an anneal as possible should be used. Annealing always damages the magnetic properties of a magnet steel. Grades of steel which are air hardening must be annealed by the fabricator after the hot forming operation if machining is to be done on the formed magnets. Otherwise, annealing may be done at the mill if forming is not required or if the machining may be done before forming. Magnet steel should be heated to the annealing temperature quickly, held at temperature only long enough to be heated through and cooled just slowly enough in the furnace to avoid air hardening. In all cases, cooling from 1000°F. to room temperature may be done in the open air, since no air hardening will take place below 1000°F.

Hardening—The recommended hardening temperatures are specified in Table I. The optimum hardening temperature is that which gives the highest value of the product $B_r \times H_c$, except that some magnets are not designed for maximum efficiency and require higher values of B_r or H_c than are associated with the maximum value of the product $B_r \times H_c$. High values of B_r are best for long or slender magnets and high values of H_c for short thick magnets. Oil quenching results in higher values of H_c and lower values of B_r than water quenching. The latter results in a much greater amount of warping, cracking, and breakage. For this reason oil quenching steels are gradually replacing water quenching steels for most applications. Magnets should not be held at the hardening temperature longer than is necessary to heat them through.

Grinding—Great care must be exercised in grinding hardened magnets to avoid the production of grinding cracks which sometimes develop hours after the grinding operation. Wet grinding and light cuts are the best safeguard against grinding cracks.

Cast Magnets—Magnets of intricate shapes, chiefly made of cobalt steel, are frequently produced by casting. The properties of cast cobalt steel do not differ greatly from those of forged or rolled steel, although the coercive force is usually higher and the residual induction lower. The same annealing and hardening practices are recommended. The cast material is generally more brittle than the forged.

Miscellaneous—Reliable correlation of microstructure with magnetic properties has not been accomplished. In general, a fine, silky fracture is associated with good material. Decarburization should of course be avoided. Heating above 212°F. after hardening is detrimental to the magnetic properties. Actual damage begins to take place at from 300-400°F. Defective magnets may frequently be reclaimed by rehardening. There is, in general, no particular way of immersing magnets quenched in water which will minimize warpage or breakage. Tongs used in quenching magnets which must be formed to size just before the quench should be as light as possible to avoid cooling the magnets too much by contact with cold metal before the quench.

Precipitation Hardening Magnet Alloys—The range of possibilities for the design of permanent magnets has been greatly extended by the introduction of substantially carbon-free alloys of the precipitation hardening type. The magnetic

properties of any of the permanent magnet steels can be substantially duplicated by some of the possible carbon-free alloys and, in addition, materials having coercive forces greatly in excess of any of the magnet steels are commercially available, with still others in process of development. The alloys appearing to have the greatest commercial possibilities at the present time are an alloy of iron, cobalt, and molybdenum; and an alloy of iron, nickel, and aluminum; or iron, nickel, cobalt, and aluminum. The former has the advantage of slightly higher coercive force and residual induction than 36% cobalt steel, greater machinability, slightly lower density and lower cost. It has the disadvantage of greater brittleness. The latter alloys have coercive forces from 2-3 times those of 36% cobalt steel and residual inductions from $\frac{1}{2}$ - $\frac{1}{2}$ those of 36% cobalt steel. They have still lower density and cost, but they have the disadvantage of being neither forgeable nor machinable. Their use is therefore confined to magnet designs which can advantageously be cast.

The above alloys may, under proper conditions, be made to produce good magnets in the cast condition without further heat treatment, but in general, a high temperature solution heat treatment terminated, in some instances, by an oil quench, but generally by a rapid cool in an air blast and followed by a precipitation heat treatment is required for best and most uniform magnetic quality. The iron-cobalt-molybdenum alloy is machinable before and after the solution heat treatment, but not after the precipitation heat treatment.

It is possible to make magnets by the process of compressing and sintering the powders of the constituent metals. This process may also be applied to the production of magnets from the oxides of the constituent metals. The metallic oxide magnets have the peculiar property of being greatly improved by being magnetized at an elevated temperature. The improvement persists for subsequent remagnetizations at room temperature.

Properties of some of the carbon-free magnet alloys are given in Table II. Other alloys which have been reported include an iron-platinum alloy with coercive force of 1800 oersteds and a residual induction of 4000 gauss, an alloy of neodymium with iron having a coercive force of 4300 oersteds and a silver-iron alloy with a coercive force of 5000 oersteds. In these cases the residual induction is so low as to practically preclude the possibility of commercial usefulness.

Table I
Commercial Types of Magnet Steels

Type of Steel	Nominal Composition ^a , %						—Nominal— Magnetic Properties		Hard- ening Temp., °F.	Quench- ing Medium	Manu- facturer
	C	Mn	Cr	W	Co	Mo	B, gauss	H _c , oersteds

The Creep of Metals and Alloys

By J. J. Kanter*

Definition of Creep—Creep is a continuing change in the deformation or deflection of a stressed member. With regard to metals and alloys, creep is generally associated with a time rate of deformation continuing under stress intensities well within the yield point, the proportional limit, or the apparent elastic limit for the temperature in question. The creep may be an effect of consequential magnitude at normal temperatures as well as at elevated temperatures, depending upon the material under consideration or the degree to which freedom from continuing deformation is sought.

Value of Creep—The first creep of metals studies of industrial importance were published by Dickenson¹ in 1922 on various steels and alloy structural members subjected to high temperatures in furnaces. His experiments served to demonstrate that commercial metallic materials, when used at elevated temperatures, underwent a steady rate of deformation under stresses well within the values allowed by good design practice and "safety factors" at that time. The creep of metals had been considered from the academic approach as early as 1910² and again³ in 1919.

As the temperatures of industrial processes steadily advanced and it was realized that troublesome deformations and even failures of equipment were being experienced at supposedly safe design stresses, critical inquiry into the behavior of metals at elevated temperatures was initiated. In 1924, realizing the industrial importance of these problems, the A.S.M.E. and the A.S.T.M. established a standing research committee for studying the effects of temperature upon metals which has sponsored two symposia,^{4,5} numerous reports, and technical papers.

At first, it was felt that practical stresses, below which creep either did not take place or was of inconsequential magnitude, could be determined for the various materials at elevated temperatures. Creep investigations made from this point of view were published by Lea⁶ in 1927 and French⁷ in 1926 which purported to show that proportional limits determined with sufficient delicacy might be regarded as "creep limits." Investigations published in 1928 by Kanter and Spring,⁸ in which

refinements of creep measurements had been made, showed that considerable rates of creep could be measured at stresses well below the lowest proportional limits determinable by the most delicate means available. At the higher temperatures, an increasing disparity between short time tensile test values and usable creep stress values was demonstrated, as illustrated in Fig. 1 by data for annealed cast carbon steel.⁹ It is now a commonly accepted fact that short time tensile test stress values are unreliable design criteria for elevated temperature use and that values determined by actual long time creep testing are to be preferred. Although working stresses based upon tensile strength "safety factors" are still authoritatively used as bases of design stress for the temperatures up to which creep is of inconsequential magnitude, the accepted basis of design for the higher temperatures is the selection of creep stress values. A summary of the status of creep studies in 1937 is to be found in the proceedings of the International Association for Testing Materials.⁹

Character of Creep—The bulk of available information on the character of creep has been gained from observations upon bars under constant tensile load and at

Fig. 1—Annealed cast carbon steel.

*Research Metallurgist, Crane Co., Chicago.

constant temperature. Extensive studies have been made of the interrelation between creep strain, stress, and temperature by testing series of specimens under various combinations of load and temperature. A creep test is generally conducted for sufficient time to establish the character of the creep strain versus time curve at the particular constant load and temperature in question. Such a test, to be of significance, may require anywhere from a few days to several years. Tests of less than one thousand hours duration are not generally regarded as of much significance in reliably establishing creep rates.

Fig. 2—Typical tensile creep curves obtained under different loadings for two alloy steels.

The second stage of creep is that strain occurring either at a constant rate or in asymptotic approach to a constant rate. The design of stressed members is generally based upon the rate of second stage creep strain. The useful life of a structure is for some purposes adjudged to be the time elapsed before the termination of the second stage. In Fig. 2 the upper curve shows second stage commencing at slightly less than 2,000 hours at a total creep of about one per cent and terminating slightly beyond 3,000 hours at a total creep of about 1.4%, where the rate of straining commences to increase. The lower curve shows no increase of rate up to 5,000 hours and tests are available in which the creep of metal specimens has continued in the second stage for several times this period. During the second stage of tensile creep the cross sectional area of the specimen remains sensibly unaltered, and thus the constant load creep rate is usually reported for practical purposes as a constant stress creep rate.

The third stage of creep is marked by an accelerating creep rate, leading to fracture. Although stress intensification and "necking" of the section contribute in the promotion of third stage creep, studies upon numerous materials have tended to show that this stage is generally reached at deformations much smaller than those sufficient to produce rapid creep to fracture through stress intensification only. Such evidence is held to be indicative of marked structural changes which strain, time, and temperature produce in metals and alloys.

Numerous mathematical discussions of the shapes of creep curves have appeared; noteworthy among these are papers by McVetty¹⁰ and Weaver.¹¹

Creep Stress—The practical aim of creep testing is generally the determination of stress intensities, at temperatures of interest, upon application of which the amount of deformation occurring is limited to tolerance values over a period of time comparable to the anticipated working life of the member to be designed. Creep stresses, as so defined, are generally based upon the rate of creep measured in the second stage and are justified as design values upon the assumption that deformation during the useful life of the equipment is largely confined to this approximately uniform rate of creep. For some materials and purposes of application the deformation accumulating in the first stage must be taken into account. Constant rate creep stress then becomes inapplicable and other creep stress values

In Fig. 2 are illustrated two typical tensile creep curves based upon results actually obtained under different loadings on two different alloy steels at high temperature. The strain designated as "total creep" is the net plastic deformation accumulated over and above the elastic strain immediately incident to the application of load. The initial creep upon a specimen not previously strained is invariably rapid, but as the straining progresses, the rate of creep decelerates until after an appreciable period a constant rate is approximated. This initial straining at a decreasing rate is frequently designated as the first stage of creep.

based upon the total deformation for the life period are desired. The bulk of available creep stress data, however, has been determined in terms of either the constant creep rate or tangents to the time deformation curve determined for some arbitrarily chosen time of test. An example of creep stress data for steel at elevated temperature is shown in Fig. 1, wherein a comparison with short time tensile strength, proportional limit, and yield point values is drawn.

Creep Testing Methods and Apparatus—The modifications of apparatus used in obtaining information upon metals vary widely in form and purpose. Although most study has been given creep under constant tensile load and temperature, numerous arrangements of apparatus have been devised for measurements in torsion, transverse bending, internal pressure, relaxation, variable loading, and variable temperature. Ample descriptions of the equipment used for tensile creep testing up to 1931 are given by Tapsell.¹² Since the publication of the Tapsell book, there have appeared a number of papers describing advances in tensile creep testing technique such as given in references 13, 14, 15, 16, 17, 18, 9, 19.

The A.S.T.M. has tentatively set up a creep testing code²⁰ for the guidance of investigators seeking to evaluate the tensile creep characteristics of metals. No attempt has been made in the code to prescribe a definite method of procedure or to specify apparatus, but rather to point out some of the possibilities, limitations, and pitfalls of creep testing. It is recognized that creep investigation is still largely a subject for metallurgical research and no hard and fast code rules can be set up which might not prove detrimental to the best interests of progressive research. Indeed, a newly proposed revision of the A.S.T.M. tentative method²¹ attempts to cover only such fundamental considerations as the amount of extension, the effect of temperature, the tensile stress, and the time. It is annotated in this new A.S.T.M. method that since the characteristics which render a material resistant to extension under the condition of test are not yet completely known, the only details of the procedure considered are those known to be important influences, and since others equally important may in the future be discovered, the recommended details of the method are largely advisory in nature.

Considerable latitude of practice among various investigators is found with regard to the choice of test specimens. The gage lengths in use generally vary from 2-20 in., while diameters vary from 0.252 to 0.505 in. Longer gage lengths are preferred for delicacy of measurement where minute creep rates are of interest. For metallurgical comparison purposes where the order of creep resistance is of primary concern, the 2 in. gage length is usually employed, as not only is the problem of specimen procurement simplified, but also easier test bar furnace and measurement technique may be employed. The 0.505 in. dia. specimen is generally preferred to the 0.252 in. because errors incurred due to scaling and consequent effect on cross section constitute less of an error.

Determination of the temperature of the specimen during the test is recognized by the A.S.T.M. code as the most important single measurement in connection with creep testing, because small variations in temperature may produce large changes in creep rate. Care must be taken to insure accurate temperature measurement over the gage length of the specimen throughout the test. Reliable temperature measurements must be made at sufficiently frequent intervals to insure an accurate determination of the average test temperature.

It should be here noted that a great part of the creep data to be found at present in the literature was obtained under conditions of test not acceptable under the proposed code. A confusion of creep values is to be found for certain compositions of steel. While much of the discrepancy is traceable to differences of heat treatment and other manufacturing variables, a goodly part of the disagreement must be attributed to lack of standardized technique and careful control of testing temperature.

Extension measurements are made through a number of devices, such as microscopes focussed on targets within the furnace or extension arms extending beyond the furnace actuating either optical levers or micrometer dial gages. Where total extensions are limited to the same order of magnitude as elastic extensions, it is important to have the elastic portion of the total extension accurately known.

The proposed revised A.S.T.M. code for creep testing, recognizing that much information pertinent to the intelligent evaluation of creep information has been lost through inadequate descriptions of materials used, recommends that essential information for identification of the materials tested be collected on a form which provides not only a most complete description of the material as to form, composi-

tion, and physical properties, but all manner of grain size information, manufacturing data, and auxiliary test information. The code also adopts a tabular arrangement for the reporting of the characteristics of the equipment used, intended to reflect the essential qualities of the measurements obtained.

Reliability of Creep Data—Considerable difficulty has been encountered by engineers seeking to use creep data, such difficulty being occasioned frequently by widely varying creep stress values for a given grade of material issuing from different authoritative sources. There has come about some reluctance on the part of creep investigators to attempt predictions of service behavior beyond the period of actual test until more knowledge is gained on how to measure reproducibly actual creep rates among the various laboratories.

Inconsistencies in creep data and testing are gradually being mastered, however, through cooperative efforts of various investigators and the Joint Research Committee (A.S.M.E.-A.S.T.M.) on Effect of Temperature on the Properties of Metals. A number of research projects are being carried forward through the donation of funds and work by industry and are directed toward systematically determining some of the perplexing difficulties encountered in the application of creep information.

Fig. 3—Time elongation curves for a 0.35% carbon steel at 850°F. under stress of 7,500 psi. The curve numbers indicate the different laboratories.

A recent report¹¹ of this committee bears much of the fruit which has come of its efforts. In this report, an appendix prepared by C. L. Clark covers a series of creep tests on annealed 0.35% carbon steel at 850°F. under a stress of 7,500 psi. The bar steel used in the tests was prepared by one of the co-operating manufacturers with extreme precaution to insure uniformity of properties from test bar to test bar. Samples were distributed among various co-operating laboratories for test at 850°F. and 7,500 psi. stress. Laboratories reporting curves for this uniform material, measured in strict accordance with the provision of the Tentative A.S.T.M. Creep Test Method E22-35T were in excellent agreement as attested by the chart reproduced in Fig. 3. The steel used in this work, it is stated, was of at least as high a degree of uniformity as is possible to secure commercially under the present knowledge of melting practice, and the results obtained from the tests at 850°F. are in good agreement when the comparisons are based on creep strength. The conclusion is drawn from these results, however, that the creep rate and deformation characteristics are too sensitive an index of strength to permit exact duplication either in different laboratories or in duplicate tests in the same laboratory.

Factors in the Materials Tested Which May Influence Creep—In a carefully prepared preamble to the Joint A.S.M.E.-A.S.T.M. Committee's compilation¹² are summarized the factors which experience indicates must be considered as having a possible influence on the high temperature creep characteristics of steels. The factors so treated include melting process and practice, heat treatment, chemical composition, grain size, duration of test, number of tests, and various other influences.

In an appendix to the Joint Committee report,¹⁷ studies on the effects of manufacturing variables on the creep resistance of steels by H. C. Cross and J. G. Lowther emphatically demonstrate the effects which variation in austenite grain size may have upon creep rate. The results for the same 0.35% carbon steel for which creep curves are shown in Fig. 3 are summarized in Fig. 4, the spread between the rates designated for "coarse grain" and "fine grain" representing the decrease in creep rate of a steel effected through grain coarsening treatments. Similar conclusions were reached by Weaver²² with regard to the effect of what he describes as carbide grain size on the creep resistance of steels conforming to the S.A.E. 4330 at 840°F. General conclusions as to the effect of grain and carbide coarsening treatments whether affected by heat treatment through transformations or by recrystallization after cold working were reached by Kanter and Spring in 1928.^{5, 23} The profound effect which microstructure may have upon creep resistance is marked in studies upon alloy bolting steels where two heat treated structures of the same bar showing similar short time tensile test values may show widely variant creep strengths. In creep stress comparisons at 1000°F. the fine structure resulting from an oil quench and temper will sustain only one-quarter of the load permissible for

Fig. 4—Same 0.35% carbon steel as Fig. 3 with creep curves summarized.

the coarse structure obtained by a normalize and temper. A noteworthy study of the effect of heat treatment is to be found in a paper by Miller, Campbell, Aborn, and Wright.¹⁸

Source of Creep Data—The Joint A.S.M.E.-A.S.T.M. Research Committee on Effect of Temperature on the Properties of Metals undertook comprehensive compilation of creep data²⁴ from as many sources as could be reached. All laboratories known to be engaged in creep work, both in the United States and Europe, were canvassed for contributions to this compilation. The data were requested to be submitted to the committee compiled upon the A.S.T.M. creep test report form as adopted in the proposed revised code. Hitherto unpublished data were obtained for the compilation in this canvass. Additional valuable information was gained to supplement other data available in earlier literature. All information was critically co-ordinated with published data and assembled under the sponsorship of the Committee at the University of Michigan under the directorship of C. L. Clark. This book, over 900 pages in content, presents 430 sheets of test data, 270 graphs, and 73 tables covering wrought and cast carbon and alloy steels, including stainless steels and cast iron and nonferrous metals. (See also review by W. A. Baker.²⁵) All creep rate stress data are summarized upon log-log charts. Creep stress versus temperature charts showing comparison upon the basis of both composition and treatments are made for each class of material where data made available at the time of compilation permitted. This compilation has been published in its entirety by the A.S.T.M. and the A.S.M.E. A comprehensive tabulation of creep stress data is also to be found in a paper by Chadwick.²⁶ Other sources of data are listed in the appended references.

Acceptability Tests for High Temperature—Since it is impracticable to make a long time creep test on each heat of steel or heat treatment charge intended for service at high temperatures, considerable thought and study is being given to the development of some method of test which will assure that a particular lot of a given material has creep properties consistent with those dictated by the design requirement to which the material is being applied. The requirements for such a test are that it can be performed within 24 hr., that it will detect off-color heats of material and that the conditions of test, reproducibility of results, and correlation with creep data are such that mutual agreement can be reached between manufacturer and purchaser. A number of papers on the subject of the development of such tests have appeared by C. L. Clark, A. E. White, and others. An appendix of the Joint A.S.M.E.-A.S.T.M. Committee Report²⁷ summarizes the results of rapid time-to-fracture tests in comparison with long time creep tests on several steels. At this writing it is premature to draw conclusions on the general usefulness of such tests for specification purposes. The results are encouraging, however, and it probably will only be a matter of time until enough experience will be gained for various grades of materials to interpret brief time-to-rupture tests in the light of long time behavior. Noteworthy efforts to develop short "time-yield" stresses for acceptance purposes have been made by Hatfield²⁸ and some of the German investigators.²⁹

Fig. 5—Short rupture time test results in contrast to regular creep test. Annealed S.A.E. 1015 electric furnace steel, tested at 1000°F.

not usually show a stress for rupture less than would be chosen on a creep test basis unless a high creep rate is allowed. However, for the longer time intervals, the rupture strength gets to be considerably less than might be anticipated by some of the rules for selecting design stresses. The "life test" or "time-to-rupture" test can throw a good deal of light on the boundary region between strength tests and creep tests. Such tests make possible the determination, in certain instances, of which is the more important consideration, the possibility of rupture or excessive distortion. Since life tests and creep tests are distinctly different in character, representing quite different considerations, it is important to distinguish clearly the significance and value of each type of test. There appear but few cases, unfortunately, in which extended life tests have been carried out to deformations leading to rupture as were the tests depicted in Fig. 5.

Utilization of Creep Data—Space does not permit a digest of the mathematical and engineering theories and experiments bearing on the application of creep data. A rather extensive literature on this phase of the subject is to be found. A paper by Kanter,³⁰ prepared as a digest of the uses of creep results, contains numerous references to the work published up to 1936. Since 1936 a number of new papers on the applied mechanics of creep have appeared, some of which may be found in the Transactions of the A.S.M.E. such as papers by C. R. Soderberg, A. Nadai, J. Marin, and others dealing with applications of creep to compound stress systems, transverse bending, pressure tubes, flanges, relaxations of bolts, and various other special problems.

Allowable Working Stresses Based on Creep Data—The Boiler Code Committee of the A.S.M.E. proposes to revise allowable working stresses for ferrous materials used at elevated temperatures in accordance with the best available creep data. The creep data compilations of the Joint A.S.M.E.-A.S.T.M. Research Committee on Effect of Temperature on the Properties of Metals are used for this purpose. Allowable working stresses applying to steels at elevated temperature have been tentatively proposed³⁰ for inclusion in the A.S.M.E. Power Boiler Code. A diagram giving these working stresses at various temperatures is reproduced in Fig. 6 in which the steels are identified by their A.S.M.E. and A.S.T.M. specification numbers. The solid lines represent the various grades of carbon steel, with the exception of

Fig. 6—Diagram giving working stresses for steels according to the A.S.M.E. and A.S.T.M. specifications.

A203-37T, which is 2½% nickel steel. The dotted lines represent various grades of carbon-molybdenum steel. The same allowable stress for any grade of carbon steel applies to all temperatures from 650°F. to -10°F. and is based upon one-fifth of the nominal tensile strength for forged and rolled material and one-seventh of the nominal tensile strength for cast materials. In the case of carbon-molybdenum steel grades these same rules apply to the temperature range 800°F. to -10°F. Above these temperatures (650°F. and 800°F.) the curves are based, conservatively upon creep stresses and the best experience. It will be noted that all the curves converge toward four common lines at the higher temperatures. The lower group of solid lines and the lower dotted line represent cast grades. These cast grades are rated more conservatively than corresponding forged or rolled compositions, but actually possess creep resistance equal to or greater than the wrought compositions. Allowable working stress ratings for elevated temperatures upon additional alloys, as well as extensions upon the proposals shown, are contemplated by the A.S.M.E. Boiler Code Committee after sufficient study of the creep data compilations has been made.

Mass Influence in Heat Treatment

By E. J. Janitzky*

With an increase in the mass of steel of the same shape and composition, there is a corresponding change of physical properties when such pieces are quenched under identical conditions.¹ For example, if a series of round bars of different diameters of S.A.E. 1045 steel are quenched from the same temperature by the same procedure into the same quenching medium, the physical properties of the quenched bars will vary in a regular manner dependent on the diameters of the rounds. This difference will also be evident, although different in value, after the usual tempering operation. This difference in physical properties is due to the rate of decomposition of austenite, which has been shown by Bain² to be very slow at the beginning of the transformation (100% austenite), increasing to a maximum at about 50% transformation and again becoming slow as the reaction nears completion (Fig. 1). Alloys such as nickel³, chromium⁴, and manganese⁵ increase the hardenability in the same size and shape of piece, that is, makes the steel deep hardening, and they effect the rate of decomposition of austenite.

The hardenability as measured by a hardness test depends not only on the diameter of the section which is heat treated but also on the depth within the piece at which the hardness is measured if the section is large enough so that it has not hardened completely, that is, to the center. This would also be true of physical properties such as tensile strength, yield point, elongation and reduction of area if they were to be determined at different depths within the piece. Characteristic hardenability curves⁶ are shown in Fig. 2 in which the Rockwell "C" hardness of water quenched rounds of various diameters are plotted against diameter of the section. Fig. 2 shows a plain carbon steel, S.A.E. 1045, at the left, and a deep hardening alloy steel, S.A.E. 6140 at the right. In $\frac{1}{2}$ in. round the S.A.E. 6140 has hardened completely and in 1 in. round nearly so. In $\frac{1}{2}$ and 1 in. rounds of

Fig. 1—Direct comparison of reaction time in a nickel and a manganese steel. Both steels contained about 0.55% carbon and 3.8% alloy. (Bain²)

section is increased and, after reaching a maximum, decreases again as the mass becomes so great that the steel is practically inert to heat treatment.

Tensile strength and elastic limit will decrease with increase in the diameter of the section while elongation and reduction of area will increase. In bars smaller in diameter than one which will just harden completely, there is relatively little change in physical properties with size in commercial quenching operations. In the sizes which fall somewhat short of complete hardening, the change in physical properties with size is relatively rapid but diminishes as the size is increased until the mass becomes so great that the steel is practically inert to heat treatment. Alloying with chromium, nickel, or manganese counteracts this inertness while combinations of chromium, nickel, or manganese with vanadium, molybdenum, or tungsten may or may not have deep hardening potentialities, depending on the composition, grain size and heating temperature.

Suppose that a series of rounds of S.A.E. 1045 and a similar series of rounds of an alloy steel, such as S.A.E. 2340, have been quenched under identical conditions.

Fig. 2—Hardenability curves in which the Rockwell hardness is plotted against the diameter of the sections. (Grossman.⁴)

Fig. 3—Relationship between tensile strength and diameter of sections for several steels.

A series of physical properties changing with increasing size will be obtained for each steel. However the physical properties of the S.A.E. 2340 series will be different in value for identical diameter than in the S.A.E. 1045 series due to the presence of nickel in the S.A.E. 2340 steel. Similar effect will be obtained by the use of any of the alloys mentioned above although the value of the change in hardenability will depend on the alloying element and its percentage in the steel together with the carbon content of the steel. These alloys affect not only the hardenability in quenching but also cause the steel to resist tempering more than do plain carbon steels.

The relationship between tensile strength and diameter of section for S.A.E. 1045 and several common alloy steels is shown in Fig. 3. These steels were normalized, then quenched from appropriate temperatures into oil or water as indicated and tempered at 1000°F. The oil quenched specimens are underscored in Fig. 3. The tensile tests were taken from midway between center and surface of the quenched and tempered rounds except for the 1 in. rounds in which the tests were taken from the center. It is evident that the decrement in tensile strength in each steel bears a regular relationship to the increase in diameter of the section. The following relationship was observed: As the diameter of the section increases in arithmetic progression, the tensile strength decreases in hyperbolic order according to the following equation:

$$P_2 = P_1 \left(\frac{d_1}{d_2} \right)^n$$

in which P_1 = the tensile strength corresponding to the diameter d_1 and
 P_2 = the tensile strength corresponding to the diameter d_2 .
 n = exponent (different for each curve).

The Marked Similarity in Tensile Properties of Several Heat Treated S.A.E. Steels

By E. J. Janitzky* and M. Baeyertz†

The effect of increasing tempering temperature on the tensile properties of heat treated S.A.E. structural steels is usually represented by a series of charts, each chart applying to one carbon content within one S.A.E. type. With the growth of our knowledge of the tensile properties of plain carbon and alloy steels, however, it has become evident that the tensile properties of one might almost be substituted for those of another *provided* that the appropriate heat treatment for each has been applied. This has seemed to justify the following attempt to assemble these numerous tensile property charts into a few charts which show *general relationships* applicable to the S.A.E. structural steels as a group.

The charts presented have been assembled from data on test specimens of S.A.E. structural steels which have been heat treated in a definite manner. Such heat treatment is necessary in order to obtain interchangeability of the tempered steels on the basis of tensile properties. The requisite heat treatment may be any commercial quenching operation *provided* that the steel and the section be such that the test specimen used will *harden throughout when quenched*. The nature of the quenching is immaterial provided that the cooling rate is such that the resulting structure is martensite, which in many instances undoubtedly contains more or less retained austenite. Thus a given section of an oil hardening steel which will harden throughout if quenched in oil will also harden throughout if quenched in water. On the other hand, a given section of a water hardening steel which will harden throughout if quenched in water *may not harden throughout if quenched in oil*. This is caused by the greater hardenability of oil hardening steels as compared to water hardening steels. It is not customary, because of the high stresses developed, to harden thoroughly as large sections in water as in oil; hence oil hardening steels will harden throughout by oil quenching in much larger sections than are feasible by water quenching the so-called water hardening steels. In fact this is the property which has led the engineer to group steels in water hardening and oil hardening grades. If test bars of the S.A.E. structural steels are hardened throughout and are then tempered to the same tensile strength, they will have the same yield

Fig. 1—Data on the tensile properties of several S.A.E. water hardening steels. One inch round bars were normalized, quenched in water, according to S.A.E. recommendations, then tempered at various temperatures from 400-1300°F.

Prepared for the Subcommittee on Alloy Elements, the membership of which was as follows: Jerome Strauss, Chairman; H. B. Knowlton, Walter Crafts, J. W. Sands, E. C. Bain, A. J. Herzog, L. L. Ferrall, E. J. Janitzky, and C. H. Herty, Jr.

strength, the same elongation, and somewhat the same reduction of area *provided* that the tensile strength is below about 200,000 psi. This is illustrated by Fig. 1, 2 and 3. Moreover, if tempered to the same tensile strength, they will have the same Brinell hardness as shown by Fig. 4.

Fig. 1 shows the assembled data on the tensile properties of various S.A.E. water hardening grades. One inch round bars were normalized, quenched in water, according to S.A.E. recommendations, and then tempered at a series of tempering temperatures from 400-1300°F. The tensile properties were determined on standard 2 in. x .500 in. ± .005 in. dia. tensile test pieces machined from these bars. Without regard to the tempering temperature required to produce any given tensile strength, the tensile strength of each test piece has been plotted (Fig. 1) against the yield strength, elongation, and reduction of area obtained on the same test piece. Fig 1 shows that there is little difference between the various S.A.E. grades with regard to the other tensile properties which accompany a given tensile strength *provided* that a tensile strength of 200,000 psi. is not exceeded. It should be noted, however, that the *tempering temperature* required to produce any given tensile strength may be different for the different S.A.E. grades.

Fig. 2—Data on the tensile properties of several S.A.E. oil hardening steels. One inch round bars were normalized, quenched in oil, according to S.A.E. recommendations, then tempered at various temperatures from 400-1300°F.

Fig. 3—Data from Fig. 1 and 2 on water and oil hardening steels plotted on a single diagram.

Above a tensile strength of about 200,000 psi., steels tempered to the same tensile strength have the same yield strength and elongation, but the reduction of area becomes an independently variable property depending on the individual steel. It is our belief that this variation is the result of retention of a variable amount of *austenite on quenching*, and the structural features which accompany the decomposition of such retained austenite at low tempering temperatures.

Fig. 4—Brinell hardness plotted against tensile strength for the steels shown in Fig. 1 and 2.

ening and oil hardening S.A.E. steels on the basis of tensile properties, provided that the steels are quenched in such a manner that each steel will harden throughout.

Fig. 4 shows the Brinell hardness number plotted against the tensile strength for the same steels as shown in Fig. 3. It is apparent that water hardening and oil hardening steels, if hardened throughout and then tempered to the same tensile strength, are interchangeable on the basis of Brinell hardness.

One point remains for discussion, namely, the change in tensile strength with increase in tempering temperature. This relationship is shown in Fig. 5 for the various water hardening and oil hardening grades, using the same experimental data as in Fig. 1 and 2. Many of the points in Fig. 5 would have been superimposed if they had been plotted exactly on the 100°F. steps of tempering temperature which were actually used in testing. The designation for the various steels have therefore been grouped around each tempering temperature while their exact position in relation to the tensile strength axis has been retained. Under the experimental conditions imposed, the tempering temperature required to produce a given tensile strength is a function both of the alloy content and the carbon con-

Fig. 2 shows a compilation of similar data for various oil hardening grades quenched in oil in one inch rounds, according to S.A.E. recommendations, and then tempered. Again there is little difference in tensile properties between the various grades, provided that the test bars are tempered to the same tensile strength and provided that a tensile strength of 200,000 psi. is not exceeded.

Fig. 3 comprises all the data on water hardening steels in Fig. 1 and on oil hardening steels in Fig. 2, plotted on a single diagram. Because of the larger number of experimental points, the designations representing the individual S.A.E. grades have been abandoned and circles have been used to indicate all experimental points. Fig. 3 shows the interchangeability of quenched and tempered water hard-

Fig. 5—Change in tensile strength with increase in tempering temperature for water and oil hardening steels. The specimens were held at temperature for 30 minutes.

tent of each steel. This relationship must therefore be determined experimentally.

An example of the use of the figures just presented may not be amiss. Suppose, for instance, one desires to obtain a given tensile strength using one of these S.A.E. steels as hardened throughout and tempered in one inch round section. It follows from Fig. 3 and 4 that the accompanying yield strength, elongation, reduction of area and Brinell hardness number will also be fixed within narrow limits provided that a tensile strength of 200,000 psi. is not exceeded. Thus if a tensile strength of 170,000 psi. is desired, then according to Fig. 1, 2 and 3 the yield strength will be approximately 150,000 psi., the elongation will be approximately 16%, the reduction of area will be approximately 54%, and according to Fig. 4 the Brinell hardness number will be approximately 350, no matter which of these S.A.E. steels is used *provided* only that the steel shall be *hardened throughout* prior to tempering. The tempering temperature which is required to obtain this tensile strength and accompanying properties, however, *will vary with the steel used* according to Fig. 5. For example, using S.A.E. 2330 the tempering temperature required to obtain a tensile strength of 170,000 psi. is 800°F., while S.A.E. 6130 must be tempered at 900°F. and S.A.E. 4145 at 1000°F. in order to obtain a tensile strength of 170,000 psi.

It will be evident from the foregoing discussion that the S.A.E. structural steels are substantially equivalent on the basis of mechanical properties as determined by the tensile test under the following conditions:

1. If the sections are so chosen that the test pieces of each steel are *hardened throughout on quenching*.
2. If the test pieces are *tempered to the same tensile strength*, irrespective of the tempering temperature necessary to produce that tensile strength.
3. If a tensile strength of 200,000 psi. is *not exceeded*. Under the above conditions of quenching, the tempering temperature required to obtain a given tensile strength depends both on the alloy and the carbon content of the steel and must be determined experimentally

The Alloying Elements in Steel

By Edgar C. Bain*

The metal iron, exceeded in abundance by only three other elements in the earth's crust, has been reduced from its ores largely by the agency of carbon, even from its earliest utilization; for a high yield of iron carbon is employed plentifully. Therefore the products of the reduction carry carbon—together with small amounts of such other associated elements as carry through the process or are introduced from the fuel and reducing agent and even the operation of oxidizing away the undesired portion of the carbon in steel making may permit some of the impurities to remain. Thus, practically, iron is found in commerce not as a high purity metal, but chiefly as a metal with a moderate degree of "impurity." These unsought accompanying elements and such amounts of correctives as are used to facilitate steel making are not generally regarded as forming an alloy steel. Of all the elements, it is this same inexpensive carbon which appears to have the most pronounced and generally speaking, beneficial effect, upon the physical properties of the element iron.

Iron, then, not so much in spite of as because of its impurities, forms, with increasing carbon (say 0.03-4.0%) a series of alloys, first steels and finally cast iron, which provide an array of materials unparalleled in variety and applicability. But such limitations as do exist in this amazing series of metals may be greatly extended by the intentional incorporation of some proportion of other of the elements, principally, though not wholly, the metallic ones. These alloying elements as advisedly added to iron and steel enhance the desired properties in the resulting alloy steels (and iron), and below are some of the specific objectives toward which the alloy additions in steel are directed.

- A. Enhancement of Mechanical Properties.
 - 1. Increase in strength of steel as manufactured.
 - 2. Increase in toughness or plasticity in steel with any minimum hardness or strength.
 - 3. Increase of allowable maximum section which may be quench-hardened to desired properties.
 - 4. Decrease in quench-hardening capacity.
 - 5. Increase in rate of hardening with cold work.
 - 6. Decrease in plasticity at given hardness in the interest of machinability.
 - 7. Increase in abrasion resistance or cutting capacity.
 - 8. Decrease in warping and cracking in development of desired hardness.
 - 9. Improvement of physical properties at either high or low temperatures.
- B. Enhancement of Magnetic Properties.
 - 1. Increase in initial permeability and maximum induction.
 - 2. Decrease in coercive force, hysteresis and watt loss (magnetically "soft" iron).
 - 3. Increase in coercive force and remanence (permanent magnets).
 - 4. Decrease of all magnetic responses.
- C. Enhancement of Chemical Inertness.
 - 1. Decrease of rusting in moist environment.
 - 2. Decrease of attack at elevated temperature.
 - 3. Decrease of special attack by chemical reagents.

The foregoing examples are engineering desiderata and contain no clue to the actual physical-metallurgical effects of the alloying elements which ultimately bring about these useful engineering advances. A study of the articles on the individual steels immediately following this section will amply show that no element, merely by its benign presence alone, commands a degree of hardness, softness, toughness, brittleness or compatible combinations without regard to its effect upon the structure of the resulting alloy steel. For this reason, the articles on the individual alloys and their respective alloy steels have much to do with constitution diagrams; with the microstructural phases, which are favored by one element, opposed by another, or even eliminated. It may well be stressed that the rates of the reactions occurring in the heating and cooling, be it a mere cooling from the rolls or a quench and temper, are of just as great importance as the reactions themselves and that the most powerful means of controlling these rates lies in alloying elements. Accordingly particular enlightenment may be secured by a comparison of the equilibrium diagrams with the constitutional diagrams showing the constitution of the various alloy steels after specific representative treatments.

*Asst. to Vice Pres., United States Steel Corp., Pittsburgh.

Although the following chapters show that the tremendously important individual physical characteristics of alloy steels are not simply conferred by the added elements, there are nevertheless only a limited number of things these elements may do, only a few ways in which they may exert their great influence upon the steel; and accordingly the philosophy of alloy steels is probably not in fact complex, for all its ultimate variety. This chapter sets forth this philosophy for the medium carbon, medium alloy steels which constitute the major tonnage.

While a comparatively small proportion of an alloying element usually suffices to modify appreciably the properties of steel in some manner, some of them make their presence manifest at far lower concentration than that required for others. When relatively very large amounts of the alloying elements are present the characteristic behaviors of the carbon steels are generally obliterated and such high alloy steels will not be treated in detail here, however important they may be; their behaviors and properties are so individually characteristic, and so far removed from those of carbon steel as to warrant the special treatment they receive in other chapters. In this category will be found Hadfield's high manganese steel, Invar (iron-nickel), and the austenitic stainless steel family, as well as the low carbon, high chromium alloy steels (chromium in excess of about 15%) which are not subject to the allotropic change characteristic of carbon and medium alloy steels.

Under the chapter "The Iron-Carbon Alloys" it will be seen that annealed carbon steel consists of two essential substances: (1) Soft, alpha iron (ferrite), and (2) hard, iron carbide (cementite), both of which may carry dissolved elements. In addition there are usually some nonmetallic particles which (fortunately) prevent too great grain growth in the steel, and which (unfortunately) occasionally assume microscopic dimensions which are regarded as undesirably large. When suitably heated, such steels undergo the well known transformation in which the ferrite and the carbide mutually react to form a single, new solid solution,—austenite. Upon cooling, the austenite reverts to ferrite and carbide, but with a range of characteristics which exceeds in variety that known in any other metallic system. Even in carbon steel, carrying roughly half of one per cent carbon, the hardness may be so great as to enable it to scratch glass or so low as to permit easy deformation,—a range due almost wholly to structure, that is, to the fineness and mode of the carbon (carbide) distribution. How then do the alloying elements superimpose their vast effects upon this control of structure? Clearly the first requisite is a knowledge of the distribution of the elements in the phases of the steel.

Distribution and Effects in Annealed Steel—In the annealed steels under discussion here, the alloying element has clearly a limited choice as to its location, that is, as to how it can distribute itself. It may be:

1. Dissolved in the ferrite:
Al, Si, Ni, Cu, P, and Co (Zr) very largely; Cu not in excess of some ¼%; Mn, Cr partially; largely so with low carbon content; nearly all elements in customary proportion in low carbon steel except S, O and high Cu.
2. Combined (if carbon is sufficient) in the cementite or special carbide phase:
Ti, V, Nb, Ta, W, Mo largely; Mn, Cr in part, depending upon carbon content.
3. Combined with other elements to form special compounds and nonmetallics:
Al in Al_2O_3 or aluminum silicate; Si in SiO_2 and silicates, Zr in ZrO_2 , V in oxide, et cetera; Cr in $Cr_2O_3 \cdot M_2O_3$ in high chromium steel; Ti, Zr, V, and high Al in nitrides, S in sulphides; possibly Si and Ni, Al and Ni, Cr and Si in corresponding intermetallic compounds when present in large amount in low carbon steel.
4. Dispersed in elemental form (rare):
Cu in excess of some 0.75%;
Pb under some conditions.

It is essential that it be realized that these categories are nonexclusive; in principle each element may be in three (or more) phases as indeed clearly manganese not infrequently is. The elements listed under each phase are merely those which are particularly prone by nature to concentrate there. Generally speaking, the most insoluble (inactive) state forms preferentially until one or the other elements involved approaches depletion after which the element concentrates in the remaining possible locations. Thus titanium will form carbide, nitride or oxide until it is largely exhausted or the carbon, nitrogen or oxygen nears depletion whereafter the remaining titanium will be dissolved in ferrite. Aluminum will combine with most of the oxygen and nitrogen; if some then remains it will be dissolved in ferrite since it is not found in the carbide phase. Very little nickel

is found either in inclusions or in the carbide. Silicon combines with much of the oxygen and the remainder is largely dissolved in ferrite for it is not a carbide forming element in steel. Obviously the location of the carbide forming elements depends upon the carbon content, and the deoxidizing elements will be found in ferrite only when present in relative excess of the oxygen. To repeat, trends only are shown above; the actual distribution depends upon the amount of the element present relative to the amount of other elements, on the basis of the partition coefficients of the phases. Nevertheless the distribution pattern is highly characteristic for each element.

Metallographic Effects of the Elements According to Distribution. (Annealed Steel)—In Ferrite—All of the elements as dissolved in ferrite increase its hardness and strength and, in differing degree, most of them simultaneously reduce its ductility. This mode of strengthening iron is mild by comparison with that of an effective dispersion of hard particles, but it does not take as great a toll in plasticity. Nickel, for example, is exceedingly sparing in its impairment of ductility. The effect of elements in solid solution in the ferrite matrix is best studied in a series of nearly carbon free alloys, although it may also be evaluated in higher carbon alloys if the same carbide volume and distribution is maintained in all compositions. Other effects, described beyond, may be superimposed upon the solid solution effect.

It is probably not generally realized how little of the extra strength of some alloy steels is contributed through the solid solution effect; yet high strength structural steels to be welded without special precautions must derive a large share of their strength improvement from this effect.

In Cementite or Carbide Phase—In one respect the different varieties of metallic carbides found in annealed alloy steel are similar. They appear to increase the total hardness and strength similarly for equal volumes and size of particles; all are relatively so hard that this would be expected, even though some are more voluminous than others for the same carbon content and may resist abrasion or function in cutting tools somewhat differently. The several elements, however, which appear in the carbide phase (be it the cementite or a special crystal form) have a vast disparity in diffusion rate, and therefore in the amount of coalescence occurring under like conditions. No element, so far as is known, joins with carbon (and iron) in forming a carbide with greater diffusivity than pure cementite, Fe_3C . This circumstance is suggestively consistent with the "weakness" of the pure compound Fe_3C which is always more or less undecided whether to form or dissociate.

In Nonmetallic Compounds—In the annealed alloy steels the nonmetallic compounds exert comparatively little influence upon properties except to contribute slightly to hardness or if in excessive amount in the form of threads, to decreased transverse ductility. It is in part this same adverse effect which results in improved machinability. The important role of the nonmetallic particles is discussed in the next paragraphs.

Distribution of Elements at Elevated Temperature—When the alloy steels are heated, as in hot working or for hardening, into the temperature range for complete or maximum austenite formation much the same changes occur as in carbon steel. Certain elements raise this requisite minimum temperature range, others lower it, that is, for the substantial disappearance of ferrite and solution of some or all of the carbide. In low carbon steels with sufficient proportions of the elements more soluble in ferrite than in austenite some ferrite may persist at all temperatures but these are borderline alloys approaching those not within the present scope. At suitable austenite forming temperatures the alloying elements are then found:

1. Dissolved in the gamma iron solid solution:
Nearly all elements seemingly dissolve in at least small proportion, and most of them in large amount, except as partially combined to form strong carbide compounds in higher carbon steels or as nonmetallic compounds.
2. Combined with carbon to form persistently insoluble carbides:
Ti, Ta, Nb, and V, largely with high or even medium carbon; Mo, W partially, depending upon carbon content.
3. Combined with other elements to form special compounds or nonmetallics:
Al in Al_2O_3 or aluminum silicate,
Zr in ZrO_2 , V in oxide,
Si in SiO_2 in silicates (somewhat dissolved),
Cr in Cr_2O_3 , MnO , in high chromium steel,
S in special sulphides,
Ti, Al and Zr in nitrides (somewhat dissolved).

Much of the previous discussion of the distribution of the elements in annealed steel applies here in principle, except that the carbide phases are vastly more soluble in austenite than in ferrite, and some nonmetallic inclusions are dissolved. So far as is known no element increases the solubility of carbon beyond the maximum 1.7% in pure iron-carbon alloys. All the strong carbide forming elements greatly reduce the maximum solubility of the carbide phase. It is not at all uncommon to quench such alloy steels with considerable carbide still undissolved.

Metallographic Effects of the Elements According to Distribution at Elevated Temperature (Above or Near Upper Critical)—*In Austenite*—When the annealed alloy steel is suitably heated the elements previously in the ferrite are at once incorporated into the austenite as well as all such elements as were combined in such carbide as may dissolve. In the case of nickel, copper, and manganese steels and certain chromium steels the temperature for complete austenite formation is lowered below that of pure iron-carbon alloys; the other elements raise the temperature. In alloy steels wherein all carbide disappears there is metallographically little difference from the austenite of carbon steel except as to rate of formation, homogeneity and grain size. Certain elements are said to coarsen the austenite grain, but this impression almost certainly results from the customary higher heating temperature employed or to prior effects having to do with attendant change in the nonmetallic content. When much fine carbide, either by intentional suppression of heating temperature or time, or by virtue of its low solubility, remains undissolved the austenite grain size remains fine, or, at least, does not increase much from the initial magnitude. The principal effect of the alloying elements dissolved in austenite has to do with the transformation rate upon cooling, an important subject which is discussed in subsequent paragraphs.

In the Carbide Phase—When the alloying elements are to be found in considerable portion in the carbide phase the resulting carbide is less soluble at any certain temperature than that of the cementite of plain carbon steel. Thus at heat treating temperature such undissolved carbide robs the austenite of both carbon and alloying element. Such undissolved carbide particles may serve a good purpose, as in high speed steel. The effect of undissolved carbide may be great in that little grain growth in the austenite beyond its initial fine grain size occurs while any considerable number of fine special carbide particles remain. It is probably due to this circumstance that the vanadium, tungsten, and molybdenum steels are generally fine grained; the carbide is usually not wholly dissolved—when it is, coarsening may begin at once. At exceedingly high temperature the grain may coarsen somewhat whether or not some carbide remains, as in high speed steel, for the last carbide particles to dissolve are the large, and therefore ineffective ones. Other important effects are in turn brought about by austenitic grain size and these are treated in the following section.

In Nonmetallic Inclusions—Some nonmetallic inclusions increase in solubility when the metal is heated well into the temperature range for the austenitic condition. With solubility raised and diffusivity inevitably increasing it is not surprising that some coalescence of inclusions takes place in austenite. Other inclusions, notably the aluminum compounds, coalesce exceedingly slowly; indeed, aluminum itself diffuses slowly, which may be somewhat the same thing in essence.

The most important function of inclusions, particularly the fine ones, is that of restricting grain growth. The example usually cited is that of thoria particles in tungsten and the effect is spoken of as "grain growth obstruction." This designation may be descriptive but scarcely aids in suggesting a mechanism* for the preservation of fine grains at higher temperature when the solid solution carries a dispersion of foreign particles.

Dispersed particles raise the temperature of grain growth but usually bring about a greater abrupt coarsening when coarsening does occur. For this reason, nonmetallic inclusions are of importance in steel and the significant point is that exceedingly small amounts of inclusion forming elements, notably aluminum in the presence of oxygen, or perhaps nitrogen, may alter the characteristics of a steel profoundly by virtue of grain growth effects. Nonmetallic particles may be more effective than insoluble carbide particles in the restraint of grain growth.

*Perhaps the particles, by providing copious nucleation during recrystallization upon heating, merely contrive to produce a grain system wherein all the fine grains are of substantially the same small size and consequently there is no family sufficiently smaller than the others as to merge with them and thus cause grain growth.

Alloying Elements in Hardening—Thus far, it may appear, no very profound changes in physical characteristics have been traced to the alloying elements although the valuable solid solution type of hardening of ferrite and certain grain growth effects of special carbides and inclusions have been noted. The considerable solubility of many of the elements in austenite and the effect upon austenite grain size of others have been pointed out, however, and herein lies, by all odds, the greatest of the effects of alloying elements.

Alloys Dissolved in Austenite—It has been explained in many recent publications how austenite, upon cooling, does not immediately transform when it reaches a temperature at which ferrite and carbide (not austenite) are stable, but that it delays during a period of so-called nucleation. Accordingly it is possible to utilize this period of lag to cool the piece to a temperature as low as 200°F. or lower, before transformation begins and when this is accomplished the steel is hardened. The product is then not lamellar pearlite (with or without proeutectoid constituents) as would in carbon steel have formed near the critical temperature; instead, hard martensite is formed. The interior of a piece of steel cools more slowly than the surface layers and often, when a piece is quenched and superficially hardened, it transforms near the center at temperatures (A_r') producing the softer ferrite carbide aggregate. The larger the section quenched the slower all zones cool in any medium so the hardened exterior is relatively thinner in large sections. The cooling rate, necessary to prevent the A_r' transformation and enforce the low temperature transformation, at A_r' , to martensite is called the "critical cooling rate." The temperature range which identifies this critical rate obviously lies between the critical temperature and that at which the A_r' reaction is most rapid, that is, for carbon steels from 1330°F. to around 930-1020°F. One may say then that hardenability is a function of maximum transformation rate in the A_r' range and accordingly, of the critical cooling rate in the active temperature range.

So far as known, all elements, except cobalt, when dissolved in austenite (of any certain grain size) decrease the maximum A_r' transformation rate, decrease the critical cooling rate and therefore increase hardenability. How cobalt is an exception is not known but it appears to confer a specific mobility to the crystal resulting in high transformation rate. The elements vary in this respect as to effectiveness. Nickel, aluminum, silicon, chromium, and manganese (somewhat in order of increasing effectiveness) are moderate in effect, while curiously enough, when actually dissolved, the carbide forming elements are exceedingly effective, so that the amount actually dissolved need be only relatively small to accomplish a considerable increase in hardenability. Grossmann has communicated that an increase of silicon from 0.16-0.32% resulted in a change of depth of hardening in a 1% in. round of 0.60% carbon steel from $\frac{1}{4}$ - $\frac{1}{2}$ in. An increase of 1% manganese in a tool steel may permit oil hardening instead of water quenching. The rate of transformation may be so decreased by alloying elements that heavy billets as cooled in the air will not transform except at temperatures so low as to form the harder, acicular structure. In a somewhat different category are the large additions of nickel, manganese or combinations with chromium which prevent all transformation even at low temperature, so that the alloy is persistently austenitic.*

This same hardenability effect operates to alter the lamellar, pearlitic structures which result from cooling at subcritical rates. A low transformation rate permits the steel to cool to a lower temperature before the transformation sets in and as a result a pearlite of finer lamellar spacing, and therefore of higher hardness, is produced. This feature is taken advantage of in such high strength steels as are not specially heat treated but used as cooled from rolling or normalizing temperature. In such steels, generally hypoeutectoid, the proportion of free ferrite is likewise lessened with increased hardenability for any carbon content.

It should be emphasized that the effect of dissolved elements to increase hardenability is the most important basis for their use.

Alloys in Undissolved Carbide—It has been shown that many carbide-forming alloys greatly reduce the solubility (and incidentally the rate of solution, sometimes confused therewith) of the carbide phase in austenite, and undissolved carbide may remain at heating temperature. This means that the carbon content of the austenite

*Hardenability is a function of transformation velocity in the A_r' temperature region. In principle it is not involved at all with the retention of untransformed austenite after quenching; even carbon steels retain some austenite along with the martensite and some alloying elements, for example, manganese, cause retention of austenite to a greater extent than other additions for the same hardenability.

is correspondingly lower than that of the steel as a whole and if the carbon content is high, the austenite is likewise leaner in alloying element (such as Ti, V, Mo, W or Cr) than the over-all analysis indicates. This lack of solution of the carbon is reflected in the softer martensite produced, for martensitic hardness is influenced much more by carbon than by any other element. However, this effect is generally less important than that of undissolved carbides upon grain size.

A change in austenitic grain size from about a No. 8 to about a No. 2, A.S.T.M. standard, may slow up the transformation rate some 6-10 fold, or as a rough guide an increase of two A.S.T.M. numbers often about doubles the transformation rate for any given composition. In a carbon tool steel, for example, halving the transformation rate (decrease of two A.S.T.M. numbers) may increase the depth of hardening (based upon 55 Rockwell C) from about $\frac{1}{8}$ in. to about $\frac{1}{4}$ in. In a steel (1 in. round) of greater hardenability the same increase in grain size may, for example, raise the hardness, $\frac{1}{8}$ in. from the center, from 50 Rockwell C to 63-64. The direct evaluation of hardenability by determining transformation rates is involved with experimental complexities. The simple, practical hardenability test of penetration of martensitic hardening to measured depths in one suitably sized bar is more satisfactory and, moreover, amenable to interpretation for another size. General "laws" relating these various manifestations of the same fundamental factor are currently presented by Grossmann, Azimow and Urban.* An approximation of the depth of hardening for any size bar can be made by plotting the ratio of hardened depth to radius against the reciprocal of the diameter squared, and since this is in part nearly a straight line function, only two points are required. This method is currently being presented by Queneau and Mayo.*

To sum up, carbide particles left undissolved, or especially when they are insoluble by nature at the heating temperature, restrain grain growth and to this extent limit the hardenability of whatever austenitic composition carries them. Thus a fine grained, alloy bearing steel may have the same hardenability as a coarse grained carbon steel; the deep hardening effect of the alloy being offset by the shallow hardening effect of restricted grain size with an overall gain in toughness.

Alloys in Nonmetallic Particles—In previous sections it was pointed out how the nonmetallic particles restrict grain growth as do carbide particles and often with greater efficacy. Seemingly the alumina bearing inclusions are particularly effective in this way and accordingly yield steels of low hardenability for a given composition in alloying elements.

Alloying elements then influence hardenability in any form they may take:

1. Increase hardenability (except cobalt) as dissolved in austenite.
2. Decrease hardenability (by restricting grain growth) as incorporated in insoluble carbide particles or nonmetallic inclusions.

The effect of grain size control upon hardenability alone would scarcely be of consequence if it were not for the superior toughness of the heat treated transformation products from fine grained austenite. The energy absorbed in the breaking of two quenched and tempered bars, identical except for prior austenitic grain size, may have a ratio of 5-1 if the grain size of the tougher bar is 4 or 5 grain size numbers finer than the other. The tendency toward quenching cracks, warpage and grinding cracks is greatly reduced for any steel by a finer austenitic grain size; the superior properties are apparent in the freshly quenched martensitic condition and in the moderately tempered products as well. There is evidence that the benefits of fine grain are in large part due to internal stress, for microscopic cracks are hardly found in martensite from fine grained austenite but become increasingly prominent in coarser grained specimens.

An element which is partly dissolved and partly combined as persistent carbide may thus at once contribute deep hardenability and toughness through grain growth restriction.

Alloying Elements in Tempering—In freshly quenched steel the alloying elements are largely in the martensite; some remain in undissolved carbide and inclusions. These latter play small part in tempering. It is taken as established that the real function of tempering depends upon the formation and coalescence of carbide particles. Because of the preponderance and ubiquity of iron there can be little doubt that the first carbide particles to form (and start growth) are predominantly

*Hardenability of Alloy Steels, A.S.M., 1939.

of iron carbide, since minimum diffusion is thereby involved. Later the special carbide elements assert themselves and in some cases the Fe_3C particles are no longer exceedingly small when this occurs. Often considerable softening has occurred before the carbon migrates to form a fine dispersion of special carbide which then retards or halts the softening or causes a "secondary" hardness.

Elements which remain in the ferrite solid solution during tempering exert the solid solution effect, a strengthening with little loss in plasticity. The special carbide particles are of great importance in that their coalescence is slow, and hence the hardened alloy steel resists softening at higher temperature than does carbon steel. This makes possible high creep strength. Furthermore the stresses in the ferrite matrix (inherited from the severely stressed martensite) are doubtless greatly reduced by the higher tempering temperature possible in alloy steels (carrying carbide forming elements) when any certain degree of final hardness is sought. This alone will explain much of the superior toughness of alloy steels, though the fineness of austenitic grain is probably still more potent in enhancing plasticity and toughness in quenched and moderately tempered steel.

During tempering the alloying elements influence the steel in that they (1) dissolve in the ferrite matrix to improve strength and to resist ferrite recrystallization; and (2) form a persistently fine dispersion of more slowly coalescing special carbide which, for any hardness, allows higher tempering temperature and accompanying alleviation of internal stress in the matrix.

Nonmetallic dispersions so far as is known have practically no effect upon tempering or carbide coalescence. Very large inclusions of course are undesirable.

It is important to bear in mind that prior austenitic grain size alone has no significant effect upon the rate at which martensitic steel softens during tempering. This is due to the fact that grain size does not alter carbon diffusivity, true both for ferrite and austenite. Thus the preservation of fine grains by the use of small amounts of aluminum to form an aluminum oxide type of dispersion is found experimentally to have no effect upon the rate of carbide agglomeration at any certain temperature. When austenitic grain growth is restricted as only one manifestation of a definite alloying effect (as with vanadium) the softening during tempering is, of course, modified. In both instances, however, transformation rate, and hence transformation temperature at any particular cooling rate is changed and this difference in temperature produces a different degree of carbon diffusion.

The alloying elements serve to improve the properties of heat treated steel in still another way, that is, by bringing about acicular structures having mechanical properties superior to those of lamellar structures but still without involving first a full martensitic hardening.

Some alloy steels have certain special transformation rate characteristics by virtue of which a moderately slow continuous cooling results in transformation at a somewhat elevated temperature to a slowly formed, acicular structure,* softer than martensite, having a spheroidal carbide dispersion. Its superior properties, with or without tempering, are probably due to lower internal stress somewhat as in the direct transformation product produced in carbon and low alloy steels by rapid quenching to intermediate temperature and maintenance thereof for deliberate transformation.

Equilibria in Alloy Steels—While it cannot be denied that a knowledge of the influence exerted by the several alloying elements upon hardenability and grain size and thus upon the final resultant strength, and toughness of the heat treated steel is of primary importance, some interest attaches to the constitution of alloys of each element alone with iron, and a great deal more to the iron-carbon alloy ternary equilibrium and constitutional diagrams.

The principal constitutional effects of the various elements upon iron relate to melting point, α (δ) \longleftrightarrow γ (A_1) and γ \longleftrightarrow α (A_1) transformations and the magnetic change point A_2 . Depending upon whether or not the elements form iron-rich compounds and whether they restrict or widen the temperature range of the γ form of iron, they fall into a system of four categories. It must be stated, however, that the influence of an element as reflected

*The names troostite-martensite, self tempering martensite, pseudo-martensite, cubic martensite and bainite have been used to describe this structure. The last is the name applied, however, to the similar, direct transformation product of "Austempering" also mentioned in the next sentence.

in its binary alloys with iron has little to do with its important effect upon steels other than those of very low carbon content. Attempts to classify alloy steels on the basis of the binary diagrams have been almost useless. For example, it was thus erroneously assumed that nickel and manganese, which "stabilize" austenite would be the most effective retarders of transformation of austenite in medium alloy steel, whereas some of the elements which stabilize ferrite, and form carbide, are actually more effective.

With respect, however, to the ternary equilibrium diagrams, considerable needed information is here provided. The effect of the element upon the temperature necessary to produce austenite, the shifting of the eutectoid composition, the solubility of the carbide, and the compositions exhibiting special carbide, are all essential items of information in gaining acquaintance with the alloying elements in steel. There are other diagrams, based not upon equilibrium at all, but showing instead just which constituents and aggregates are actually established after specified treatments, that are even more informative. Some of these are available. It is hoped that many more will be worked out from time to time. What the equilibrium diagram cannot show is the rate of change from one condition to another with a change in temperature (for example, hardenability); it can tell nothing of the retardation of these changes due to low diffusion rates; finally, the ternary diagrams based upon pure alloys are not necessarily applicable to commercial materials which carry elements employed for steel making facility. Notwithstanding these shortcomings the philosophy of alloys in steel cannot be built up without a knowledge of the trends, and the constituency toward which the alloys move as the tendencies more and more assert themselves.

Conclusions—In the foregoing paragraphs, it has been shown that alloying elements in steel may exert only a certain few basic influences upon fundamental behavior and properties. An element may exert the usual solid solution effect toward strengthening the ferrite, or when dissolved in austenite profoundly enhance the hardenability of the steel. When the alloying element is combined with carbon (and some iron) the resulting special carbide may restrict austenite grain growth at heat treating temperature and, as formed after quenching, during tempering, it may, with benefit, necessitate and permit higher heating temperature for any certain degree of softening. As combined to form dispersed nonmetallic inclusions it may restrict grain growth or in other larger particles improve machinability. These fundamental influences serve to impart valuable engineering properties.

It might be anticipated, then, that many alloy steels intended to be heat treated are similar. Indeed when suitably heat treated to develop similar austenitic grain size and a similar hardness, the mechanical properties at ordinary temperature are almost indistinguishable as between many different analyses. The same cannot, of course, be said of chemical properties such as corrosion resistance. It is sometimes forgotten that, within its rather narrow limits of cross section, carbon steel may be so treated as to secure room temperature properties approaching those of many low and medium alloy steels. This limitation of size is, however, a serious one, and in overcoming this feature the addition of alloying elements contributes one of its foremost benefits. The effects upon fundamental mechanical properties of the alloying elements are all, so far as is known, gradual and very largely predictable in nature however critical they may seem for any particular application. The precise degree of an alloy effect will have to be determined experimentally although approximate interpolation of properties for intermediate proportions is not impossible. There are few, if any, instances wherein abrupt physical changes actually accompany slight changes in proportion of added elements and even less probable are any unexpected sharp maxima of good properties at certain ratios or proportions among the elements. There is a persistent belief, perhaps valid, that the use of two elements having similar effects instead of one somehow brings about more than the expected sum of effects. Since few alloying effects are measured in dimensions or quantities which are in nature linear or additive, this impression may be erroneous.

Table I sets forth some of the basic trends of the elements in terms of metallographic effects. These effects may be translated into property trends in light of the concepts set forth heretofore. The table refers to a fairly broad range—medium to high—of carbon content, but not to the very low carbons, and some allowance is made for the amount of element customarily employed in low and medium alloy steels.

Table I
Trends of Influence of the Alloying Elements

Chromium Steels

By Walter Crafts*

Description and Sources of Chromium—Pure chromium is a soft, fairly ductile metal with a blue-white metallic luster but the commercial forms which contain small amounts of impurities are relatively hard and brittle. Physical constants are given on page 78. It has limited use as a pure metal except as addition to non-ferrous alloys.

Chromium was first reduced to the metallic condition by Vauquelin in 1797 and was added to steel by Berthier in 1821, who immediately recognized the resulting greater hardness, magnetism, and resistance to acid. In 1822 Faraday and Stodart recognized the superior oxidation resistance. It is of interest that these properties are basically those for which chromium is used today, although their significance and useful development were not realized for almost a century.

Starting with the addition of chromium to structural steel by Baur in 1865, the commercial use of relatively small amounts of chromium in tool, ordnance, and engineering steels has increased continually. The production of low carbon ferrochromium led the way to high chromium-low carbon steels of the stainless type. Brearley developed stainless cutlery steel containing 11-14% chromium in 1913, and with the oxidation resistant chromium irons of Becket and the austenitic chromium-nickel steels of Strauss and Maurer, the application of stable surface steels containing large amounts of chromium developed in enormous strides. Resistance of these steels to food, chemical and atmospheric attack has permitted technological, mechanical, and stylistic changes whose effects on our civilization may be as yet but dimly realized.

The only industrially important chromium mineral is chromite of the nominal composition $\text{FeO} \cdot \text{Cr}_2\text{O}_3$. The ore usually occurs in massive form but frequently is found as grains in a serpentine matrix. The luster of chromite is submetallic to metallic; the density is 4.32-4.57 and the hardness is 5.5 on the Mohs scale. The ore is widely distributed although the most important sources are Turkey and Rhodesia. Although a fairly large amount of chromite was mined in the United States during the World War, the bulk of the normal requirements is supplied by other countries. For metallurgical purposes the ore should be of a massive structure, contain at least 48% Cr_2O_3 , and have a chromium to iron ratio of at least 3 to 1.

Ferrochromium containing 60 to 72% chromium is used for adding chromium to steel and is made in several grades with carbon contents ranging from 0.05 to 9%. The ore is reduced in an electric furnace, with carbon for the high carbon grades and with silicon for the low carbon alloys, to produce ferrochromium containing 60-72% chromium. A description of ferrochromium and its introduction into steel is given in the section on "Metals and Ferroalloys Used in the Manufacture of Steel".

Structural Influence of Chromium in Steel and Cast Iron—On account of its utility in promoting hardness and toughness, and also wear, oxidation and corrosion resistance, chromium is commonly used in steel and cast iron in amounts ranging from a fraction of a percent to 35%. As indicated by the diagrams described in the articles on the Constitution of Iron-Chromium Alloys and Iron-Chromium-Carbon Alloys, a wide range of structural characteristics is developed, which produce marked changes in physical properties. Many extra-equilibrium structures of importance are readily obtainable by virtue of the characteristically slow rate of

Fig. 1—Constitutional diagram for chromium steels. Normalized in $\frac{1}{2}$ in. sq. sections.

*Union Carbide and Carbon Research Laboratories, Inc., Niagara Falls, N. Y.

there is also a tendency for austenite to be retained. The effect of mass is illustrated by the differences between Fig. 1 and 2. Specimens from which Fig. 2 was determined were bars approximately 1 in. in dia. which were heated to approximately 1750°F. and air cooled. Significant differences between the two diagrams are restricted only to the relatively high carbon contents. General features that are common to both diagrams are the lowering of the carbon content of the eutectoid composition, development of martensitic structures over a wide range of carbon and chromium, and the range of ferritic high chromium steels that result from restriction of the austenite field.

The broad structural classifications with their approximate chromium contents are as follows: 1. Pearlitic chromium steels, -0-2%; 2. Martensitic chromium steels, -2-17%; 3. Ferritic chromium steels, -17-35%; and 4. Austenitic chromium steels, -10-30%.

These groupings are only approximate and the composition limits may be shifted by heat treatment and minor alloy additions. They are, however, sufficiently typical to serve as a basis for illustrating the many effects of chromium in improving carbon steel and conferring special properties.

Pearlitic Chromium Steel—Although chromium is usually added to pearlitic steels to increase the hardness, ductility or toughness, amounts of less than 0.50% chromium are widely used in carbon steel and the more simple alloy steels to increase moderately the hardenability. Chromium tends to reduce segregation, has a slight grain refining capacity, and has the property of making steel "normal" in the McQuaid-Ehn carburizing test. The latter property is of particular value in preserving uniform hardening capacity in steels made fine grained with aluminum.

When over 0.50% chromium is used, the greater hardenability, decreased mass effect, and toughening become more effective. In low carbon high strength structural steels chromium is typically a toughening rather than a hardening addition. It increases the impact resistance at subzero temperatures and has a specific effect

Fig. 2—Constitutional diagram of chromium steels containing 0.50% manganese normalized in 1 in. dia. bars.

on the brittleness introduced by high phosphorus contents as shown in Fig. 3. The corrosion resistance conferred by phosphorus and copper is enhanced by chromium, although the tendency of chromium to impart corrosion resistance is barely appreciable at 1% chromium unless some special condition, such as abrasion, is involved.

Chromium carburizing steels are used in applications requiring a high degree of surface hardness and wear resistance. S.A.E. 5120 is used for general purposes, and higher chromium steels are used for severe duty where higher core strengths are necessary. Chromium is also used in complex carburizing steels containing vanadium, molybdenum, nickel, and manganese.

Heat treated 1% chromium engineering steels of the S.A.E. 5100 types develop appreciable freedom from mass effect at a relatively low cost and are of specific value for wear and fatigue resistance at moderately high strengths in structural parts, springs, and gears. Modified 1% chromium steels of the S.A.E. 3100, 4100 and 6100 types also have wide application for similar purposes. Higher chromium contents are less widely used, but find application in articles of larger section. The 2% chromium-vanadium steel used in pressure vessels for ammonia and alcohol synthesis is especially resistant to hydrogen embrittlement. Some application of steels containing about 2% chromium is also made, usually in conjunction with other alloys, in moderately severe elevated temperature service.

Chromium has long been used in tool steels in order to obtain extreme hardness, as in drills, chisels, and files. Such steels are deep hardening and where toughness is desirable are made with a fine grain size. Chromium is also used in low tungsten chisel, die and finishing steels to improve the hardening characteristics. Superior wear resistance, which seems to be a specific property of chromium carbide, makes 1-2% chromium of considerable value in tool steels for rolls, shearing dies, and certain types of cutting tools. Ball bearing steel is the preeminent application of this kind and contains about 1% carbon and 1.5% chromium.

Somewhat larger amounts of chromium are used in hot working die steels to increase the hardening capacity and wear resistance. Both tungsten and molybdenum types of high speed steel contain about 4% chromium, which controls to a major degree the hardenability of the steel and is an essential factor in developing adequate toughness and hardness. It also facilitates heat treatment, assists in the formation of well distributed small carbide particles and improves the retention of red hardness.

Steels containing approximately 1% carbon and from 1-5% chromium are the most widely used of the permanent magnet steels. Where practical, the steels are hardened in water to develop the best magnetic properties, although oil hardening is the usual treatment. Although the best properties are obtained at about 3% chromium, the economical balance has been found to lie at about 2% chromium.

Chromium both alone and in conjunction with other alloys is used in cast iron to improve the strength, wear resistance, and thermal stability. In the range of 0.5%, chromium increases the strength by reduction in size of the flake graphite and the retention of more pearlite. The matrix in the areas of eutectic graphite is made pearlitic so that the sources of excessive wear are largely eliminated. The breakdown in structure after prolonged heating is minimized by chromium. Above about 0.75%, chromium produces primary carbides in gray iron that make machining difficult, and higher amounts produce a wear resistant white iron. Irons containing

Fig. 3—Effect of chromium on normalized steel containing 0.10% C, 0.35% Mn, 0.09% P, and 0.80% Si.

1-2% chromium are resistant to wear and moderately severe high temperature service and are used for applications such as grinding balls, grate bars, and incinerator parts.

Martensitic Chromium Steels—The martensitic range of chromium steels containing 2-17% chromium is used for almost as broad a variety of applications as the pearlitic steels, although the utility depends in greater degree on the surface stability conferred by chromium. With higher chromium, the effect of mass, and resistance to wear, corrosion, and oxidation, increases.

Steel containing 0.20-0.40% carbon and 2-4% chromium is pseudomartensitic in the air cooled condition and has unusually high ductility and toughness at a tensile strength of about 180,000 psi. Railroad rails of this composition, as well as similar steels of higher carbon content, are extremely wear resistant. The high ductility at high strength is readily developed in steel castings. Steels of this chromium content, usually in conjunction with molybdenum, tungsten, silicon, aluminum, and vanadium, are used for moderately high temperature service.

More severe service requires a higher chromium content, and in oil refining stills steels of 4-6% chromium are most widely used although some steels of higher chromium content are used to combat more extreme conditions. The 4-6% chromium steel contains a carbon content of less than 0.20%. Molybdenum or tungsten is usually added to increase the creep strength at elevated temperatures, and columbium or titanium is used to stabilize the carbides and prevent air hardening. Chromium confers some strength at elevated temperatures, but its primary effect is to reduce oxidation and the corrosive effect of sour oils. The effect of chromium on oxidation resistance is illustrated in Fig. 4. Steels of the silicon-chromium type with higher carbon and higher silicon, in some cases with secondary alloys, are used for valves in internal combustion engines in which the high strength and resistance to corrosion by the combustion gases make an effective combination.

At about 12% chromium the resistance to corrosion by oxidizing media becomes much higher, and steels containing 12-18% chromium are widely used for cutlery. The low carbon grade is cold rolled to develop hardness suitable for cheaper knives. This steel also has an extremely high order of mechanical properties after heat treatment, and is used for turbine blades and valve trim. The steels containing 13% chromium with 0.30-0.40% carbon, and 16-18% chromium with 0.60-0.80% carbon are used for the better grades of cutlery and for a variety of purposes requiring high strength, oxidation and corrosion resistance. They must be fully hardened and free from surface imperfections to develop maximum corrosion resistance. With modifying elements such as nickel, molybdenum, and vanadium the steels are even more suitable for cutlery and articles such as valve parts and ball bearings where wear is severe. Steels containing carbon up to 2% are also used in tools, rolls, and dies to avoid excessive wear. Modifying alloys are commonly used. The steel can be annealed for machining and is hardened by oil quenching followed by tempering to secure appropriate properties.

Ferritic Chromium Steels—When the chromium content exceeds 16-17%, austenite formation is largely restricted as shown in Fig. 1 and 2, and the structure consists primarily of ferrite that is not transformed to austenite at elevated temperatures. The low carbon steel does not harden readily and can be cold worked to an unusual degree especially when the small percentage of carbon present is fixed with columbium or titanium. The steel containing 18% chromium is widely used on account of its great corrosion resistance, and higher chromium contents up to 28% are used for oxidation resistance at high temperatures. The latter steel is subject to grain growth at elevated temperatures and if so heated is quite brittle unless the steel is given a persistently fine grain size by the addition of nitrogen. These steels have found application in furnace construction, and heat exchangers for resistance to oxidation and sulphur-bearing gases at temperatures up to 2100°F., and for resistance to mine water and mixed acids at ordinary temperatures.

Higher carbon increases the oxidation and wear resistance, and a large proportion of the steel in the range of 15-30% chromium is used in the form of castings

Fig. 4—Effect of increasing chromium on oxidation resistance.

with 1.00-2.50% carbon. High chromium cast iron is one of the most abrasion resistant of the ferrous materials, and is used for such parts as sand blast equipment and piercing points.

A more recently developed application of ferritic steel is the alloy containing 37% chromium and 7½% aluminum for resistors in electric furnaces. While the alloy has a low strength, it resists oxidation at temperatures up to 2370°F.

Austenitic Chromium Steels—Due to the sluggish manner in which high chromium steels transform, it is possible, by the addition of metals such as nickel, manganese, and copper, to produce and retain exceedingly persistent austenite by moderately rapid cooling from 1825-2190°F. The austenitic chromium steels have an extremely high order of corrosion and oxidation resistance. They have exceptionally good cold working properties, are adaptable to severe deep drawing operations, and are suitable for use in the cold rolled condition if high strength is required. The steels have the low magnetic susceptibility and the high coefficient of expansion typical of austenite. Due to their ease of fabrication by welding, bending, forming, or spinning, the austenitic steels have enjoyed the widest range of application of any of the stainless steels.

The most popular composition contains 18% chromium and 8% nickel. Several other steels ranging up to 25% each of chromium and nickel are also used. Higher chromium is required to gain further oxidation resistance, and more nickel is added to obtain greater austenite stability and greater strength at elevated temperatures. Steels similar to 18-8 have also been developed where manganese and copper are substituted for all or a part of the nickel. These steels have good drawing properties and are more resistant to sulphur-bearing atmosphere than the 18% chromium-8% nickel steels. The chromium-manganese steel has a structure consisting partially of austenite and partially of ferrite. Other additions are made to austenitic chromium steels for specific purposes. Columbium or titanium is added to prevent susceptibility to intergranular corrosion during heating in the range of 575-1650°F. Molybdenum, tungsten, and copper confer additional corrosion resistance. Aluminum and silicon may be used to increase the oxidation resistance. Selenium and sulphur improve the machinability.

The austenitic chromium steels are used primarily for acid resistance in chemical and food handling plants, for furnace parts, and for architectural trim. The corrosion resistance and high strength of cold worked austenitic chromium steel make possible the use of light box type structural members of great strength and stiffness. Although this type of construction is being developed for uses where weight is a primary factor, as in aircraft, railroad cars, and ships, it is evidently destined to play a large role in other applications.

Stainless Steel*

(Castings Not Included)

By Owen K. Parmiter†

Less than 20 years ago, the term "Stainless Steel" referred to but one type of corrosion resistant material. The steel contained 0.35% carbon and 13.50% chromium. Today, the number has increased to upwards of 60 different compositions including types for practically every application requiring a heat or corrosion resistant steel.

So rapid has been the progress in developing new combinations and types that it is difficult to decide at this time upon the relative importance and merits of many of them. Limited space confines this discussion to about 16 representative types whose value has been established. These are briefly described, special consideration being given to composition, heat treatment, and general physical properties.

Series of Straight Chromium-Iron Alloys—All of the corrosion resistant steels included in this series possess a comparatively low degree of heat conductivity and a high resistance to the softening action of heat, the combined effect of which makes forging somewhat difficult. In addition to this, the high carbon types harden readily in air after forging, which necessitates a softening or annealing operation before further fabrication. Each of the following "type compositions" requires heat treatment to bring out its maximum properties. Aside from those particular steels that require a definite hardening treatment, most of the various types are furnished by the manufacturer heat treated ready for use.

5% Chromium-Iron—This composition was developed as an intermediate type between ordinary carbon steel and stainless iron. It possesses properties that make it desirable for use in the oil refining industry. A number of modified compositions containing molybdenum, tungsten, aluminum, and copper are available.

Composition and Heat Treatment

C	Si	Mn	Cr	Mo-W-Al-Cu
0.05-0.25	0.50 max.	0.50 max.	4.00-6.00	Up to 1.00% of each as desired

Types and Applications of Chromium-Iron Steels

Type	Elements Identifying Typical Compositions, %				Other Elements	General Applications
	C	Si	Mn	Cr		
5% Chromium	0.10	0.35	0.40	5.00		Fair resistance to heat and corrosion. Preheater tubes, dampers, still bottoms, pipes, bolts, studs, tie rods, and furnace parts.
Turbine Type	0.12	0.20	0.40	12.50	Ni 0.40	High tensile strength machinery. Turbine blades, valve parts, pump rods, pistons, cutlery and tableware.
Original Cutlery Type	0.35	0.20	0.35	13.50		Table knives, scissors, spatulas, cleavers, hatchets, pump shafts, pistons and valve trim.
Modified Cutlery Type	0.70	0.40	0.45	16.50		Butcher knives, pocket knives, dental and surgical instruments.
Ball Bearing Type	1.05	0.45	0.40	17.00		All purposes where maximum resistance to abrasion is required in a corrosion resistant steel. Balls, races, valve seats, all bearing surfaces.
Poppet Valve Type No. 1	0.50	2.75	0.50	8.75	V 0.15	Internal combustion engine valves.
Poppet Valve Type No. 2	0.45	0.90	0.40	10.00	Al 1.60	Especially exhaust valves for automobiles and airplanes.
18% Chromium-Iron	0.10	0.50	0.50	18.00	Ni 0.30 max.	A soft ductile material that does not work harden readily; not as resistant as "18-8", but useful for interior work.
28% Chromium-Iron	0.15	0.50	0.50	28.00	Ni 0.30 max.	For all applications where strength and toughness are secondary to high temperature resistance, such as furnace parts and glass molds.

(Hard Types
Martensitic and Semi-Martensitic)(Soft Types
Ferritic and Semi-Ferritic)

Types and Applications of Chromium-Nickel-Iron Steels (Austenitic)

Elements Identifying Typical Compositions					General Applications
C	Si	Mn	Cr	Ni	
Max.					
0.25	1.25	0.75	8.50	22.00	Adapted to salt water and sulphuric acid resistance, for ship parts, periscope tubes, pump shafts, and valve trim in the oil industry.
0.20	0.50	4.00	16.00	6.00	
0.20	0.50	0.40	18.00	8.00	Culinary utensils, flat tableware, jewelry, dental and surgical instruments not requiring a sharp edge.
0.25	2.50	0.60	20.00	25.00	Available in many modified forms. A general purpose corrosion resistant material. Very useful in tubing and sheet form. In cold drawn wire it makes excellent springs.
0.20	0.50	0.60	20.00	10.00	Highly resistant to heat oxidation and chemical corrosion. Used for furnace parts, retorts, and tubes. Retains its strength and resistance at temperatures up to 2000°F.
0.20	0.50	0.60	25.00	12.00	A well balanced and useful combination of chromium and nickel. Possesses many of the valuable properties of both the higher and lower alloy content materials. Excellent resistance to both heat and corrosion.
0.20	2.00	0.60	25.00	20.00	Retains its strength and resistance at high temperatures. Adapted for oil burner parts, oil refinery, chemical plant equipment, skid rails, rollers, and other furnace parts.
					A highly efficient heat resistant steel. Used for furnace doors, muffles, retorts, skids, tubes, heat exchangers, dampers, valves, and pump parts. Recommended for temperatures up to 2100°F.

"Modified Analysis" Stainless Steels for Special Purposes

Elements Added to Those Already Present	Percentage of Additional Alloys	Purposes for Which Additional Alloys Are Incorporated
Aluminum	4.00-4.50	Increases the electrical resistance. Greatly improves the resistance to scaling at high temperatures.
Copper	1.00-4.00	Improves resistance to corrosive action of dilute hydrochloric acid, also brine and ammonium chloride solutions.
Columbium	0.60-1.50	Action similar to titanium. Greatly increases resistance to intergranular corrosion.
Manganese	3.00-5.00	Improves ductility and resistance to impact. Has strong stabilizing action. Increases corrosion resistance.
Molybdenum	1.00-4.00	Similar to tungsten in its action. Increases resistance to sulphurous and phosphoric acids also brine and hypochlorite solutions.
Selenium	0.20-0.30	Imparts free machining properties without sacrificing toughness and strength.
Silicon	0.50-3.50	Produces better workability and welding properties. Increases resistance to oxidizing action of high temperatures
Sulphur	0.30-0.40	Combined in the form of certain sulphides it greatly improves machining properties.
Titanium	0.40-0.80	Reduces warpage in sheet form. Prevents precipitation of carbides and intergranular corrosion.
Tungsten	2.50-3.50	Acts as an inhibitor of intercrystalline attack. Increases strength at elevated temperatures. Improves resistance to sea water corrosion.

combines a high degree of strength and elasticity without any loss of toughness and machinability. Some resistance to corrosion, however, is sacrificed for this excellent balance of physical properties. In the cold rolled, work hardened state, this type is used extensively for the cheaper grades of cutlery.

Original Cutlery Type—This is the original stainless steel described by Brearley in his patent. It serves as an ideal material for many purposes. In order to bring out its maximum resistance to corrosion, it is necessary to harden and then thoroughly grind and polish it. This type can be made reasonably hard but is not capable of the same intense hardness possible with carbon tool steel.

As this particular steel is air hardening, it must be annealed after forging if machine work is required. In all heating operations it is necessary to preheat and then hold longer at the required heat than with ordinary steel. Forging is accomplished with more difficulty than with carbon steel. Frequent reheating is advisable.

Grinding has an important bearing on the ability of hardened stainless steels to resist corrosion. Wet grinding is always preferred, and it must be deep and thorough. Every trace of scale and surface scale must be removed. Any remaining scale pits serve as seats for corrosion and an electrolytic action is set up which rapidly spreads over the surface of the material as rust.

Modified Cutlery Type—This type was developed in an endeavor to incorporate some of the advantages of carbon steel into stainless material without sacrificing the quality of resisting corrosion. In most respects it works quite similarly to the original cutlery type, except that a more intense hardness and a better cutting edge are possible. This modified composition for stainless cutlery is used principally in hot rolled double bevels.

Ball Bearing Type—This special composition is adapted for purposes where hardness and resistance to abrasion are required in a corrosion resistant steel. This type is capable of a hardness up to as high as 62 C Rockwell in small cross sections and in this state shows excellent noncorrosive properties.

It is recommended particularly for balls, valve seats, and wearing surfaces in general where maximum abrasion resistance is demanded in a stainless steel. It has found particularly valuable application in the oil industry for needle and check valve parts in oil lines. This type is the hardest form of stainless steel.

Composition and Heat Treatment

C	Si	Mn	Cr	Mo	V
0.90-1.10	0.45	0.40	15.00-18.00	0.60 optional	0.25 optional

Operation	Temp. Range, °F.	Approx. Brinell Hardness No.
Forging	1850-1700	...
Softening	1450-1500	325
Semiannealing	1600-1650	250
Full annealing	1700-1750	225
Preheating	1400-1450	...
Hardening	1825-1925	(max.) 625
Tempering	300- 800—To suit purpose.	

18% Chromium-Iron—This nonhardening alloy is highly malleable and ductile. It is used for parts where great strength is secondary to corrosion resistance and workability. It is useful for drop forgings, cold upset articles, sheets and tubing. It does not work harden to the same degree as "18-8" and, therefore, is tougher after cold heading operations. This characteristic is of considerable advantage in many cases.

Composition and Heat Treatment

C	Si	Mn	Cr	Ni

Specific gravity	7.70
Coefficient of expansion (per °C., 0°C.-600°C.).....	0.0000117
Thermal conductivity	Approx. ½ that of ordinary steel.

28% Chromium-Iron—This 28% chromium alloy is recommended for high temperature applications. While it shows a remarkable resistance to oxidation at temperatures up to about 2000°F., it has a tendency to lose strength at such elevated heats and, therefore, should not be used for installations where high strength and toughness are requisites. It possesses excellent noncorrosive properties and is recommended for its resistance to acid mine water, mixed acids, and to sulphur gases at high temperatures.

Series of Chromium-Nickel Iron Alloys—The representative types contained in this group of highly resistant chromium-nickel alloys include various combinations of chromium and nickel in amounts ranging from 8.00-25.00% of each. Many modified forms of these high chromium-nickel steels have been developed for special purposes. These include additions of aluminum, copper, columbium, manganese, molybdenum, selenium, silicon, sulphur, titanium, and tungsten. These additional alloys have a marked effect upon the structure and heat and corrosion resistance of the resultant steel but in most cases little or no effect upon its forging or heat treatment.

All of the high chromium-nickel combinations are austenitic and possess the usual characteristics of that type, namely, low heat conductivity, comparatively high coefficient of expansion, nonmagnetic properties, inability to harden by heat treatment, good workhardening properties, and satisfactory toughness. Like other austenitic steels with the exception of the 8.50% Cr-22.00% Ni type, they are annealed or fully softened by cooling rapidly from a high temperature, usually about 2000°F. These steels of the austenitic group require prolonged soaking during both the preheat and initial heat for forging.

0.08-0.20	0.75 max.	1.00 max	17.00-19.00	7.00-9.00	0.125	0.250

The improved machinability of this type over the standard "18-8" composition has been obtained with a slight loss of corrosion resistance, but without sacrificing strength or toughness. It can be drilled, tapped, threaded, and machined with ordinary machine tools and practice. In automatic screw machines, recommended speeds are about 70% of those used on ordinary screw stock. This free machining type is recommended for general machine parts, including screws, bolts, nuts, pump shafts, valve trim, bushings, and spindles.

Free Machining "18-8" shows about the same physical properties as the standard composition and the same heat treating instructions apply.

Wrought Heat Resisting Steels*

Introduction—Carbon steels, which offer a wide selection of mechanical properties at room temperature, lose their valuable characteristics at elevated temperatures with the result that the mechanical properties tend to seek equilibrium and the effect of initial heat treatment is more or less eliminated, depending on service temperature. Wherever carbon steels are unsatisfactory for use at elevated temperatures either because of insufficient strength or lack of satisfactory corrosion or oxidation resistance, it is customary to turn to alloy steels, either low alloy additions of molybdenum, chromium, or silicon, or for more severe service conditions, the higher chromium stainless alloys such as 12%, 17%, 27% Cr, 18% Cr-8% Ni, 25% Cr-12% Ni, 25% Cr-20% Ni, and modifications thereof. The modifications may incorporate additions of such elements as titanium, columbium, molybdenum, tungsten, or silicon for specific purposes such as stabilizing carbides, increasing strength or scaling resistance. Nitrogen may be added to retard grain growth, particularly in the 27% chromium alloy. Other alloys having less than 50% iron content, for example, nickel-base alloys such as 35% Ni, 15% Cr; 65% Ni, 15% Cr; and 80% Cr, 20% Ni are used for heat resisting purposes especially for metallic resistors, furnace parts, carburizing boxes and are covered in other articles in this Handbook.

Carbon, one of the most mobile elements encountered in ferrous metallurgy, because of its atomic dimensions, is unstable at elevated temperatures both chemically and constitutionally; witness, for example, such effects as carbide aging in mild steel even at room temperatures, the prevalence of decarburization as compared to "dechromiumization" or "desiliconization," and latitude of properties obtained by heat treating eutectoid steel as compared to mild steel.

For this reason carbon is of little benefit in wrought steels for use at elevated temperatures and, except in special cases such as in carbon steel superheater tubes, alloy bolt steels and valve steels, is usually kept below 0.20% and in some cases below 0.10%. Most of the other elements described are present in solid solution in the austenite or ferrite, depending on the nature of the alloy. Thus chromium, for example, affects an inherent change in the properties of the metal apart from modifying the structural habits, that is, pearlite or troostite formation. As the chromium content of a 0.1% carbon steel is increased, one of the first noticeable contributory effects is the increased sluggishness of phase changes; 5% chromium steel is air hardening in much larger sections than mild steel because the austenite or high temperature modification persists on cooling much more than is the case for mild steel and does not usually transform until near room temperatures to yield a martensitic product. Supplementary, but entirely unrelated to this effect just described, the addition of chromium tends to reduce the rate of attack of many reagents on the metal and at about 11% addition of chromium, this change becomes so marked that the iron alloys containing more than 11% chromium have been termed "stainless steels."

Chromium is a ferrite stabilizer, that is, it acts to increase the temperature range in which ferrite is stable and with the addition of about 16% chromium, and a low carbon content, the austenite or high temperature constituent is almost completely eliminated. A higher chromium content than 16% renders the metal nonresponsive to heat treatment in the ordinary manner practiced with steel but does not prevent grain growth at the higher temperatures. Nickel is an austenite former and tends to offset the effect of chromium. The addition of about 8% nickel to an 18% chromium alloy results in the formation of austenite as the stable phase in the heat treating range of temperatures and as a result of the quantity of alloying elements present, the austenitic phase persists on cooling to room temperatures. Deforming this border-line 18-8 composition at temperatures below 300°F. causes the austenitic phase (nonmagnetic) to break down and partially transform to the ferritic phase (magnetic) but on reheating to temperatures above 1400°F., ferrite quickly reverts to austenite. Larger quantities of nickel yield completely stable austenite which does not transform on cold working.

Chromium is a carbide forming element and will readily usurp the place of iron in cementite to form a series of mixed iron carbide-chromium carbide inter-

*Prepared for the Subcommittee on Wrought Heat Resisting Steels by H. D. Newell and John J. B. Ruthertford, The Babcock & Wilcox Tube Co. The membership of the subcommittee was H. D. Newell, Chairman; R. H. Aborn, F. B. Foley, R. Franks, S. M. Heck, C. M. Johnson, E. R. Johnson, V. N. Krivobok, and N. B. Pilling.

†See the article in this Handbook on the Constitution of Iron-Chromium-Nickel Alloys.

mediate phases. Since the chromium carbide is more stable, the solubility of carbon in iron-chromium alloys is lower than in iron. About 0.03% carbon is soluble in 18-8 (austenite) at 1400°F. whereas in iron at the same temperature (also austenite) about 0.9% carbon is soluble in the austenite.

These features serve in the interpretation of the effect of temperatures on the structural behavior of these alloys. The 12% chromium alloy is amenable to heat treatment, is air hardening and fairly resistant to chemical and oxidation attack. The 17% chromium alloy is not normally amenable to heat treatment but can be hardened to a limited extent by air cooling from high temperatures (above 1800°F.). (It can be hardened in presence of sufficient carbon and/or nickel). It is more resistant to oxidation than the 12% chromium alloy. The 27% chromium steel is not amenable to heat treatment but is susceptible to embrittlement if held in the range 800-1000°F. and then tested at room temperature (this effect has been associated with the formation of an iron-chromium compound); it is still more resistant to oxidation than the other ferritic alloys. Certain of the lower chromium steels also develop cold brittleness after long heating in this range of temperature, for example 17% chromium-iron and 5% chromium steel, toughness is returned on warming or by heating to 1200°F. and rapidly cooling. Among the austenitic steels, 18-8, 25-12, and 25-20, those containing higher chromium content are more resistant to oxidation, the additional nickel content gives greater resistance to creep at elevated temperatures, to oxidation, and to chemical attack in certain media.

Resistance to Oxidation—The first prerequisite of a steel for use at elevated temperatures is resistance to oxidation. Table I gives comparative scaling temperatures for a group of steels. It should be noted that this scaling temperature is

Table I
Comparative Scaling Temperatures

25-20.....	310	0.15	1.0	0.02	0.02	0.7	25	20	2150

based on rather arbitrary standards and serves to indicate generally the lowest temperature at which, on prolonged heating in a strongly oxidizing atmosphere, a scale will form of sufficient thickness to cause flaking or spalling. These steels will oxidize at much lower temperatures forming a series of temper colors until a thin, black adherent scale layer is formed but this reaction tends to cease whereas above the scaling temperature, spalling causes progressive deterioration, thus reducing service life or making mandatory a selection of higher alloy for economical and continued operation. Compositional modifications, such as the addition of silicon or aluminum, changes the scaling temperature by changing the nature of the scale layer. A similar effect, also related to the nature of the scale product, concerns the type of atmosphere in which the metal is tested. Table II contains the results of

Table II
Scaling Tests

Test Conditions	Types

scaling tests conducted in a highly oxidizing atmosphere and, for comparison, similar tests conducted in an atmosphere of hydrogen sulphide. At these test temperatures, the chromium-rich oxide is refractory and reduces further chemical reaction while the complex sulphides formed are liquid and promote interaction between the gas and metal phases. In reducing atmospheres, where quantities of carbon monoxide are present, the scale formed is lower in chromium and therefore, offers less pro-

tection; furthermore, if carburization occurs, since carbon combines preferentially with chromium, the surface of the metal is depleted in effective chromium content and scales more rapidly. Mention may be made of the fact that under repeated heating and cooling, the ferritic stainless steels tend to scale less than austenitic steels owing to their lower coefficient of thermal expansion.

Mechanical Properties—In order to determine the mechanical properties of metals at elevated temperatures, two types of test are customarily practiced, short time tensile and creep tests. The departure from room temperature testing technique is necessitated by the fact that at temperatures above about 700°F. a new phenomenon of flow becomes operative which requires study on the basis of stress-strain-time factors at each temperature. The short time tensile test is similar in procedure to the ordinary tensile test except that the specimen is enclosed in a furnace designed to give a uniform temperature distribution held for a period of 30 min. to one hour, then, still maintained at temperature, it is pulled to fracture. Table III contains a compilation of data obtained by this type of test.

Creep Strength—Creep strength data are usually computed on the basis of the load required to obtain an elongation of 1% in either 10,000 hours or 100,000 hours depending on service requirements. The carbon steels may be satisfactory up to 800°F. or even to 1000°F.; under low stresses, low alloy steels are commonly used between 800°F. and 1100°F., above 1100°F. the extra strength and corrosion resistance of the stainless alloys generally become necessary. Table IV contains creep strength values for the stainless alloys. It should be noted that stress required to obtain a flow rate of 1% in 10,000 hours is greater than, but not in direct proportion to, the stress required for 1% in 100,000 hours. The practice of extrapolating the data in this table to different temperature ranges, flow rates, or composition is not recommended.

Table IV
Creep Strength Data

Temp., °F.	0.11% C 12 Cr	0.10% C 17 Cr	0.20% C 27 Cr	0.08% C 18-8	25-12	0.12% C 25-20

1200	1,600	1,600	1,000	4,250	5,400
1350	900	900	180	1,600	2,800
1500	800

The superior creep resistance of the austenitic alloys indicates the advantage of this type for service at temperatures above 1000°F. Relatively small additions of molybdenum and silicon, for example have been observed to alter considerably the creep strength values of the various chromium and chromium-nickel alloys. In the marginal austenitic alloys, this may be due to ferrite formation brought about by the additional element. The unexpected decrease in creep resistance of the higher chromium ferritic alloys at 1200 and 1350°F. may be associated with the peculiar temper aging which occurs in this range, or even with the formation of an iron-chromium compound, since it is generally regarded that structural instability lowers creep resistance. Further, it appears that fundamentally the body-centered cubic atomic lattice arrangement (alpha ferrite) is less creep resistant than the face-centered atomic lattice arrangement (austenitic or gamma iron).

F. H. Norton has summarized his early creep test experiments as follows:

The results obtained on steels at temperatures over 1000°F. lead to the following conclusions:

1. The high chromium ferritic stainless steels have distinctly inferior creep resistance as compared with austenitic stainless steels.
2. The face-centered structure of the austenitic steels seems to offer a distinctly greater resistance to creep than the body-centered type.

3. The high chromium, high nickel type of austenitic steel seems to offer by far the most advantages in regard to creep resistance, heat resistance, and permanency of structure.
4. An increase in chromium content in ferritic stainless steel above 18% seems to decrease the creep resistance.
5. No evidence is found for a cessation of creep as the load is decreased, and the flow rate seems to decrease with the load in an exponential manner.

Fatigue Stresses—In view of the fact that rapid intermittent stresses (fatigue stresses) may have a similar effect at elevated temperatures as they have at normal temperatures, and since pulsating stresses occur at elevated temperatures in some types of service, research on this subject may appear advisable. The data in Table V are from a recent paper (J. S. Kinney, A.S.T.M. Preprint No. 46, 1938) on fatigue properties at elevated temperatures.

Table V

Endurance Limit, lb/sq. in. to 10 ⁻⁷ cycles.	58,000	49,000	43,500	27,200

Design—Permanency of the stainless alloys at elevated temperatures may be judged by oxidation and creep resistance values shown but numerous other physical properties are required by the engineers to estimate behavior at temperature rather than length of life. A group of such properties, which are believed to be quite reliable with proper interpretation, are included in Table VI. Most of these properties can be modified to a considerable extent by cold working. For example, 18-8

when severely cold worked has an expansion coefficient similar to the 17 Cr type by virtue of the change from the nonmagnetic to the magnetic condition but at temperatures above about 800°F. this change does not apply. In general, cold working is of little consequence in these alloys when used at elevated temperatures because of automatic stress relieving effects. Another factor concerning heat conductivity which is not shown in the tables is the tenacity of the oxide scale layer which frequently has been observed to offer greater resistance to heat transfer than the metal itself. In the use of bimetallic linings, heat transfer can be readily calculated if, for example, mild steel and stainless steel are welded together but in the

case of a fitted lining within which an appreciable scale layer exists, it is impossible to calculate heat transfer.

Because of the variety of design problems involved in the application of these materials to heat resisting structures, and lack of uniform methods of applying safe stress values, it is obvious that each application is a problem in itself as to selection of material for the service requirements and proper design for expected life of equipment.

Heat Resisting Castings*

(Chromium-Nickel-Iron Alloys)

All heat resisting alloys are essentially alloys of iron and chromium in which the chromium serves to inhibit high temperature corrosion. In addition to iron and chromium, most heat resisting alloys also contain nickel which has been added to intensify the action of the chromium and to enhance the physical prop-

Fig. 1 and 2—Design strength for chromium-nickel alloys.

erties of the metal. The chromium content varies from about 12-30% and the nickel content may be as low as 8% or as high as 65%. Typical compositions are as follows:

18% Cr—8% Ni.	Balance principally iron
24% Cr—12% Ni.	Balance principally iron
28% Cr—10% Ni.	Balance principally iron
25% Cr—20% Ni.	Balance principally iron
18% Cr—65% Ni.	Balance principally iron
18% Cr—35% Ni.	Balance principally iron
20% Cr—35% Ni.	Balance principally iron
18% Cr	Balance principally iron
28% Cr	Balance principally iron

In the following discussion, alloys containing more nickel than chromium will be referred to as *nickel-chromium* alloys. Those in which chromium predominates will be called *chromium-nickel* alloys and those containing only chromium and iron will be designated *straight chromium* alloys.

Chemical Stability—Of the several alloys available for high temperature service, some are more stable than others in their resistance to chemical attack depending upon the environment in which they are to function. The most common forms of chemical action encountered in commercial heating practice are oxidation, sulphurization, and carburization. These factors acting together or independently

*Prepared for the Subcommittee on Heat Resisting Castings by J. D. Corfield, Michigan Steel Castings Co. The membership of the subcommittee was as follows: Dr. O. E. Harder, Chairman; E. C. Bain, F. M. Becket, Dr. F. A. Fahrenwald, H. H. Harris, M. A. Hunter, C. M. Johnson, T. H. Nelson, N. E. Pilling, L. J. Stanbery, E. H. Stilwell, F. E. Ziegler, and R. D. Van Nordstrand.

This article was not revised for this edition.

may cause premature failure unless they have been carefully considered in selecting the alloy. Under purely oxidizing conditions any one of the three types of alloys mentioned may be used, the choice depending upon the temperature and the physical properties of the metal at elevated temperature (to be discussed later).

Under reducing conditions (in the absence of sulphur compounds) the nickel-chromium alloys are generally preferred because these alloys do not carburize readily.

In the presence of sulphur compounds, it is customary to select one of the chromium-nickel alloys. The extent to which sulphur may influence corrosion depends upon the amount present, the temperature, and the form in which it exists, usually SO_2 or H_2S . The subject of high temperature corrosion by sulphur is not well enough understood to permit other than a few general remarks, but practical experience indicates that chromium-nickel alloys are more resistant than nickel-chromium alloys and not infrequently the only alloys that can safely be

Fig. 3—Comparison of solid and trussed beams having the same load carrying capacity. Weight of beam above 75 lb.; beam below 120 lb.

used in furnaces fired with high sulphur content fuels. In general it is assumed that harmful compounds will be present if the fuel contains in excess of 1% sulphur. It is further the general opinion that the higher chromium to nickel ratio is more important under reducing than under oxidizing conditions.

High Temperature Strength—Next in importance to the question of chemical stability at high temperature is that of high temperature strength. It would be useless to select an alloy on the basis of high temperature strength alone because the physical strength of the material would be discounted by the loss of section due to progressive surface deterioration where this occurs. Conversely a material offering maximum resistance to corrosion and lacking in high temperature strength would lead to premature structural failure. But where more than one alloy is known to possess adequate resistance to corrosion under a particular set of conditions the choice should obviously be based upon physical characteristics and cost.

The straight chromium alloys compare unfavorably with the chromium-nickel and nickel-chromium compositions in the matter of high temperature strength under conditions of sustained loading. For this reason and because they may be subject to embrittlement at temperatures above 1200°F. and to grain growth at higher temperatures, the straight chromium alloys find a limited field of usefulness in high temperature applications.

Because of their nickel content the chromium-nickel alloys are in some respects more stable at high temperature than the straight chromium alloys. While these alloys may become less ductile under prolonged heating they do not become actually brittle in their cast forms unless the carbon content is sufficiently high

to permit excessive carbide precipitation at the grain boundaries. Brittleness from this cause should not be mistaken for brittleness due to carburization to which the chromium-nickel alloys are more or less susceptible, the rate increasing as the nickel content is lowered. Carbon exerts a profound strengthening effect in all chromium-nickel alloys which is achieved at the expense of ductility. For this reason it is generally preferable to limit the carbon content to that shown in the following table:

Chromium, %	Nickel, %	Carbon, % Max.
18	8	0.20
28	10	0.35
24	12	0.50

Of the above alloys, the 18-8 material is most susceptible to embrittlement due to carbide precipitation and carburization and for this reason it is not widely used at high temperature in cast forms.

Fig. 1 gives recommended design strength values for the most commonly used chromium-nickel alloys with carbon contents as indicated above.

Fig. 4—Expansion data.

The nickel-chromium alloys and most of the chromium-nickel alloys are essentially austenitic alloys by reason of their high nickel content. Consequently they are more stable at high temperature than the straight chromium compositions. The effect of carbon in promoting brittleness is less apparent in the nickel-chromium alloys although excessive carbon content involves a serious loss in high temperature strength. For this reason nickel-chromium alloy castings are usually produced with a carbon content of 0.40-0.70%. Recommended design strength values for the two best known and widely used nickel-chromium alloys are shown in Fig. 2.

The design strength values given in Fig. 1 and 2 have been developed from data largely derived from service installations. Little is known concerning the mechanism of strain at elevated temperature and from data as yet derived it is not possible to assign infallible design strength values to the various commercial heat resisting

alloys of which those already discussed are representative. Obviously "design strength" must comprehend loss of section due to corrosion which in extreme cases may approximate 10% or more per year. Design strength should also provide a margin of safety in cases of accidental overloading or overheating which may occur in spite of the most advanced methods of control. Where corrosive conditions compel the use of an unstable alloy it must be considered that the rate at which transformations adversely affecting the strength of the material take place is a function of time as well as temperature and due allowance must be made for this phenomenon in arriving at a suitable design strength value for a given temperature.

Cases in which premature failure take place due to actual lack of load carrying capacity are fortunately rare. This is due to the circumstance that most heat resisting castings must be designed within practical foundry limitations which generally compel departure from theoretical ideals. But where no such limitation exists the most dependable practice is to employ design values which have been arrived at from accumulated data covering many thousand actual installations where load, temperature, and service life are definitely known and where the "coefficient of abuse" has been included in consideration of the service life.

Casting Design—It is always preferable to design a section of symmetrical proportions such as the I-beam, rectangle, or tube instead of channels, angles, and tees which are eccentric to at least one axis. H. Klouman in the Book of Stainless Steel, p. 637, points out that the eccentric shapes cannot be produced as straight castings due to the effect of unequal cooling in the mold, nor can such

sections be put into service after straightening with assurance that they will remain straight. Hollow, circular shapes are well produced as centrifugal castings which are now available in all heat resisting analyses. Centrifugal castings are less subject to residual stresses which are retained in tubular shapes that have contracted while in a plastic condition against a relatively unyielding sand core.

Metal thickness should be as uniform as possible because nonuniformity of integral parts tends to create shrinkage strains and cavities when cooling unequally from the molten state. Such sections are predisposed to warp in service due to different rates of change of temperature in the same casting. For similar reasons solid intersections should be avoided where possible. The effect of shrinkage can be minimized by the use of carefully located chills or preferably by coring through the mass of metal at intersections.

In designing structural elements it is important that the metal be correctly disposed. Trussed girders can frequently be designed more efficiently than solid webbed beams because the lightly stressed metal near the neutral axis of the latter can be used to greater advantage in truss chords and web members operating at full design stress. In operation trussed members permit freer circulation of heat than solid webs and thus have more even temperature distribution. Carefully placed brackets and ribs will often render a light lattice structure as stable as a heavy solid element because dead weight at high temperature is a large contributing factor creating stress which frequently exceeds that due to externally applied loads. Fig. 3 shows comparison of solid and trussed beams having the same load carrying capacity.

Where choice exists as to the size of individual castings it is preferable to use several short pieces instead of one long piece, thus facilitating the casting of lighter metal sections and minimizing the possibility of warpage due to unequal temperature distribution throughout the length of the longer member. Multiple spans designed as continuous beams are objectionable because supporting elements operating at high temperature are always subject to irregular displacements relative to each other and a slight displacement of supports seriously affects the magnitude of the stresses calculated on the assumption of continuity.

Thermal Expansion—In the design of heat resisting castings it is imperative to allow for free expansion of each part. Otherwise, stresses of incalculable magnitude may arise with the certainty of failure or distortion somewhere in the structure. The coefficient of expansion for all heat resisting alloys is not constant throughout a given temperature range but for practical purposes may be considered so. Fig. 4 gives average rates of expansion for the chromium-nickel and nickel-chromium alloys included in the preceding discussion.

Copper as an Alloying Element in Steel

By C. H. Lorig*

General—Most iron ores contain copper in small amounts which enter the iron on reduction. Copper from this source appeared in many of the early irons, their long life being attributed by some to its presence. Recently the relative cheapness of copper and its marked influence on properties of iron and steel have stimulated an interest in its use as an alloy. With several previous drawbacks to their use overcome through investigations, the commercial applications for steels containing copper have increased rapidly.

Constitution of Copper Steels—The constitution of the iron-copper alloys is given in another section of this Handbook.

The constitution of alloys from the iron-rich corner of the iron-copper-carbon system is quite uncertain, although Ishiwara, Yonekura and Ishigaki (Science Report, Sendai, ser. 1, vol. 15, 1926, p. 81-114), outlined a possible iron-copper-cementite diagram. In this diagram the solid phases existing are delta iron, gamma iron or austenite, alpha iron or ferrite, iron carbide or cementite, and epsilon, the copper-rich solid solution. The system did not have a closed gamma loop. Carbon decreased the solubility of copper in liquid iron, forming a two-liquid region, and decreased the solubility of copper in solid iron.

From lattice constant determinations, Norton found the maximum solubility of copper in alpha iron at 1560°F. to be 1.4%. The solubility falls rapidly with temperature down to 1200°F., where it remains constant at 0.35%. Because at room temperature the solubility of copper in iron is small, the epsilon phase may exist in all copper steels except in those containing only a few tenths per cent of copper. The actual existence of the epsilon phase in copper steels, however, is determined somewhat by the treatments given them.

Copper raises the A_1 point and depresses the A_3 and A_{cm} points in steels. It also retards the alpha-gamma transformation. The work of the Japanese investigators indicated that the eutectoid is located approximately at 0.9% carbon and 1.9% copper at a temperature of 1290°F.

The microstructure of steels containing only a small percentage of copper does not differ greatly from that of carbon steels. A new constituent to appear, the copper-rich solid-solution epsilon, forms either a network or large particles during solidification and cooling, or tiny particles, sometimes of submicroscopic dimensions, dispersed throughout the grains when precipitated from alpha iron. Under ordinary conditions the epsilon phase contains practically no carbon and little iron.

Alloying of Copper in Steel—In the reduction of cupriferous iron ores all of the copper enters the pig iron. On the basis of this, it was suggested that the introduction of copper in amounts required for the manufacture of corrosion resistant copper steels be effected by the use of copper bearing ore in the blast furnace.

Copper may be added to steel in the form of alloys, copper bearing pig iron, or steel scrap. A widely used practice is to introduce the copper in its metallic state, as ingots, borings, scrap, baled wire, or other shapes. It may be added to the steel in the furnace, in the ladle, or in the mold. Losses of copper during the making of a heat of steel are negligible.

Effect of Copper in Steel—General—No particular difficulties or peculiarities in the making of copper steels can be ascribed to the presence of copper. In the fabrication of the steels, however, hot working difficulties at high temperatures have been noted. As an alloying element, it affects the properties of steels, particularly the corrosion resistance, and mechanical, electrical, and magnetic properties.

Mechanical Properties—The changes in mechanical properties with carbon content of normalized and of water quenched and tempered steels containing 0, 1, and 2% copper are shown in Fig. 1 and 2. For normalized steels the changes in properties for a given copper content are practically independent of the carbon, while for water quenched and drawn steels the changes, for a given copper content, decrease with carbon.

*Battelle Memorial Institute, Columbus, Ohio.

The Alloys of Iron Research Monograph, "The Alloys of Iron and Copper," by J. L. Gregg and B. N. Daniloff, McGraw-Hill Co., 1934, deals with this subject most comprehensively and, therefore, material from it was used freely in preparing this section.

For the first 0.5% copper the mechanical properties are but slightly affected, but as the copper content increases changes in properties are rapid. They reach a maximum at about 3% copper. The properties of normalized steels containing from 0.5-3.0% copper change linearly with copper content. With quenched and tempered, and annealed steels and steels tempered after normalizing rapid changes in properties occur when the copper increases from 0.5-1.2%, but further alloying with copper is appreciably less effective.

The yield strength rises with copper more rapidly than the tensile strength. For the low carbon steels it exceeds the tensile strength when the copper content approaches 3.0%.

Fig. 1—The effect of carbon and copper on mechanical properties of steels containing 0, 1, and 2% copper after normalizing at 1650°F.

The ductility of carbon steels is lowered by copper. For a given strength, however, copper reduces the ductility less rapidly than carbon. This is shown in Fig. 3 where the Charpy impact and tensile strength values for normalized carbon and copper steels are plotted.

Test data on comparatively high carbon steel containing up to 1.65% copper indicate no change in the endurance ratio.

Scattered information on the properties of cold worked copper steels and on creep and high temperature tensile properties of copper steels indicate that improvements along these lines are produced by copper.

Heat Treatment—The alloying of copper to steels does not affect their response to heat treatment nor does it materially alter the heat treating schedules adopted for unalloyed steels. The reduction in the rate of the gamma-alpha transformation

by copper permits less drastic quenching and gives the steels greater depth hardening qualities. Slow cooling on annealing or prolonged drawing treatments cause the coalescence of the copper-rich epsilon phase in medium and high copper steels which may produce appreciable changes in the structure.

Steels containing more than 0.6% and up to about 4% copper are susceptible to precipitation hardening due to the decreased solubility of copper in ferrite from the lower critical temperature to a temperature of about 1110°F. Steels with from 1.2 to about 1.5% copper are most susceptible to precipitation hardening.

To produce the supersaturated solid solution of copper in ferrite which will respond to a precipitation hardening treatment, it is unnecessary to quench. In low carbon steels, rates of cooling greater than 2°C. (3.6°F.) per min. are sufficient for maximum hardening effects, while some hardening occurs even after cooling as slow as 0.4°C. (0.7°F.) per min.

Fig. 2—The effect of carbon and copper on mechanical properties of steels containing 0, 1, and 2% copper after water quenching from 1650°F. and tempering at 1250°F.

Precipitation hardening is effected by reheating the supersaturated solid solution of copper in ferrite for a period of time, determined by the condition of the steel and the temperature, within the range of 750°-1245°F. The greatest hardness increase takes place on heating to from 840°-930°F. for from 3-20 hr.; the longer heating time being required for the lower temperature.

The maximum changes in mechanical properties resulting from precipitation hardening normalized carbon steels containing 1.5% copper are shown in Fig. 4. The tensile strength, yield strength and Brinell hardness increase; the reduction of area and elongation decrease on hardening, the effects diminishing as the carbon content of the steels increases.

Precipitation hardening in copper steels is seemingly unaffected by small quantities of many other alloying elements, but it is affected by cold working.

The precipitation of the copper increases the electric conductivity, the density, and the residual induction of the steels.

Physical Properties—The electric resistance of iron is increased with copper up to at least 0.62%. In steel the maximum resistance is attained at a copper content which is the lower, the higher the carbon content.

It is stated that magnetic properties of steels of the permanent magnet type are improved by copper. The decrease in magnetic flux on aging is somewhat smaller.

Case hardening of steels is not affected by copper, provided the surface is not oxidized and the copper content is below 3%.

Corrosion Resistance—The results of the A.S.T.M. atmospheric corrosion tests summarized by Kendall and Taylerson are given in Table I.
